Measuring Nonlinear Granger Causality in Quantiles

ABSTRACT

We introduce new measures of Granger causality in quantiles, which detect and quantify nonlinear causal effects between random variables. The measures are based on nonparametric quantile regressions and defined as logarithmic functions of restricted and unrestricted expectations of quantile check loss functions. They can easily and consistently be estimated by replacing the unknown expectations of check loss functions by their nonparametric kernel estimates. We derive a Bahadur-type representation for the nonparametric estimator of the measures. We establish the asymptotic distribution of this estimator, which can be used to build tests for the statistical significance of the measures. We also examine the properties of the latter under local alternatives. Thereafter, we show the validity of a smoothed local bootstrap that can be used in finite-sample settings to perform statistical tests. A Monte Carlo simulation study reveals that the bootstrap-based test has a good finite-sample size and power properties for a variety of data generating processes and different sample sizes. Finally, we provide an empirical application to illustrate the usefulness of measuring Granger causality in quantiles. We quantify the degree of nonlinear predictability of the quantiles of equity risk premium using the variance risk premium, unemployment rate, inflation, and the effective federal funds rate. The empirical results show that the variance risk premium and effective federal funds rate have a strong predictive power for predicting the quantiles of the risk premium when compared to that of the predictive power of the other two macro variables. In particular, the variance risk premium is able to predict the center, lower and upper quantiles of the distribution of the risk premium; however, the effective federal funds rate predicts only the lower and upper quantiles. Nevertheless, unemployment and inflation rates have no effect on the quantiles of the risk premium.

Keywords: Measures of Granger causality; Granger causality in quantiles; nonlinear causality in quantiles; conditional quantile function; time series; local linear estimator; smoothed local bootstrap.

1 Introduction

The concept of causality, introduced by Wiener (1956) and Granger (1969), constitutes a basic notion for
analyzing dynamic relationships between time series. An examination of Wiener-Granger causality reveals
that predictability is the central issue and is of great importance to economists, policymakers, and investors.
Many studies have investigated the building of the tests of Granger non-causality. However, once it has been
established that a “causal relationship” exists, it is usually important to assess its strength. Few studies have
proposed to measure the parametric and nonparametric Granger causality in terms of the mean between the
variables of interest; refer to Geweke (1982, 1984), Dufour and Taamouti (2010), and Song and Taamouti
(2016). However, these studies ignore or pay less attention to the causality that can occur at other levels
or aspects of the conditional distribution, such as conditional quantiles. Unfortunately, we cannot use the
existing measures to quantify the strength of causality in quantiles. Thus, this study introduces the measures
of Granger causality in quantiles and, particularly, proposes model-free measures to quantify both linear and
nonlinear Granger causality in quantiles.

Unfortunately, causality tests fail to accomplish the task of quantifying the degree of Granger causality
between the variables of interest because they only provide the evidence on the presence of causality. A
large effect may not, at a given level, be statistically significant. Further, a statistically significant effect
may be neither “large” from an economic or (in general) a subject at hand viewpoint nor is it relevant for
decision making. In this study, beyond the acceptance or rejection of the non-causality hypotheses, which
state that certain variables do not help forecast other variables, we wish to assess the magnitude of the
forecast improvement. Further, this forecast improvement is defined in terms of a loss function (specifically,
expectation of quantile check loss function). Even if the hypothesis of no improvement (non-causality)
cannot be rejected by looking at the available data (for example, because the sample size or the structure
of the process does not allow for high test power), sizeable improvements may remain consistent with the
same data. By contrast, a statistically significant improvement may easily be produced by a large data set,
which may not be relevant from a practical viewpoint.

The topic of measuring Granger causality between random variables has not attracted much attention.
Further, most of the existing measures focus on Granger causality in terms of the mean; thus, they cannot be
used in the presence of linear and nonlinear causality in quantiles. Geweke (1982, 1984) introduce measures
of causality in terms of the mean based on linear parametric autoregressive models. Dufour and Taamouti
(2010) extend Geweke’s (1982, 1984) work to propose measures for short and long run causality in terms of
the mean using parametric ARMA models. Gouriéroux et al. (1987) build measures of causality based on
Kullback information criterion and use a parametric approach for the estimation of their measures. Polasek
(1994, 2002) show how causality measures can be computed using Akaike Information Criterion (AIC) and
a Bayesian approach. Song and Taamouti (2016) propose nonparametric measures of Granger causality in terms of the mean, extending the parametric approach of Geweke (1982, 1984) and Dufour and Taamouti (2010). Taamouti et al. (2014) propose a nonparametric estimator and test for measures of Granger causality in distribution. However, the latter measures are not informative enough regarding the level(s) (quantiles) of the conditional distribution wherein the causality exists; hence, the importance of providing measures of Granger causality in quantiles is relevant.

This study introduces measures of Granger causality in quantiles between random variables. The proposed measures are able to detect and quantify both linear and nonlinear causal effects, which can happen at any quantile of the conditional distribution of the variable of interest. The new measures are based on nonparametric quantile regressions and defined as logarithmic function of restricted and unrestricted expectations of quantile check loss functions. A consistent nonparametric estimator of these measures is defined in terms of local polynomial estimators of the expectations of check loss functions. Further, we derive a Bahadur-type representation for this nonparametric estimator and establish its asymptotic distribution, which we use to build tests for statistical significance of measures. Thereafter, we show the validity of smoothed local bootstrap that we apply to perform statistical tests in finite-sample settings. A Monte Carlo simulation study reveals that the bootstrap-based test has a good finite-sample size and power properties for a variety of data generating processes as well as different sample sizes.

Moreover, since testing that the value of measure is equal to zero is equivalent to testing for the non-causality in quantile, we consider an additional simulation exercise to compare the empirical size and power of our test with those of the nonparametric test of Granger non-causality in quantile, introduced by Jeong, Härdle and Song (2012). For the finite samples, the simulation results indicate that our test controls the size and has better power compared to that of Jeong et al.’s (2012) test.

Finally, the empirical importance of measuring nonlinear Granger causality in quantiles is illustrated. We quantify the degree of nonlinear predictability of equity risk premium using the variance risk premium, unemployment rate, inflation, and the effective federal funds rate. The empirical results show that the variance risk premium and effective federal funds rate have a strong predictive power for predicting the quantiles of risk premium compared to that of the predictive power of the other two macro variables. In particular, the variance risk premium is able to predict the center, the lower and upper quantiles of the distribution of risk premium; however, the effective federal funds rate only predicts the lower and upper quantiles. Nevertheless, unemployment rate and inflation have no effect on the quantiles (distribution) of risk premium.

The plan of the study is as follows. Section 2 provides the motivation for considering measures for linear and nonlinear Granger causality in quantiles. Section 3 presents the general theoretical framework

---

1 For the parametric tests of Granger causality in quantiles; refer to Lee and Yang (2014) and Troster (2016), among others.
that underlies the definition of measures of Granger causality in quantiles. In Section 4, we define the nonparametric measures of Granger causality in quantiles using nonparametric quantile regressions. In Section 5, we discuss the estimation of nonparametric quantile regressions, and consequently of the measures of causality in quantiles based on the local polynomial estimation of the expectations of the check loss functions. We provide the Bahadur representation of the nonparametric estimator of the measures in Section 6.1. In Section 6.2, we derive the asymptotic distribution of the latter estimator, which can be used to build tests for the statistical significance of the measures; we further study their properties under some local alternatives. In Section 7, we establish the validity of smoothed local bootstrap to improve the finite-sample performance of the asymptotic-based test. In Section 8, we extend our results to the case wherein additional control variables are considered. Section 9 presents a Monte Carlo simulation exercise to investigate the finite-sample properties of the tests of Granger causality measures. Section 10 is devoted to an empirical application and the conclusion of the results is given in Section 11. The key assumptions of the study and the proofs of the theoretical results are presented in the Appendices A and B, respectively.

2 Motivation

This study proposes measures of Granger causality in quantiles. Most of the existing measures focus on quantifying Granger causality in terms of the mean; refer to Geweke (1982, 1984), Dufour and Taamouti (2010), and Song and Taamouti (2016). Other measures have been proposed to quantify Granger causality in distribution; refer to Taamouti et al. (2014). The latter measures, however, are not informative enough of the level(s) (quantiles) of distribution wherein the causality exists. Thus, the significance of such measures is limited in the presence of Granger causality in quantiles.

We propose the measures of Granger causality in quantiles based on nonparametric quantile regression functions. Such measures can detect and quantify nonlinear causality in quantiles. To understand the importance of such measures, consider the following example.

Example 1 Consider the following mean regression model:

$$X_t = \mu + \beta X_{t-1} + (\gamma + \delta Y_{t-1}^2)^{1/2} \varepsilon_t, \text{ for some } \gamma, \delta \geq 0,$$

(1)

where $\varepsilon_t$ is normally (elliptically) distributed with mean zero and variance one. Since $\varepsilon_t$ is normally distributed, $X_t$ is also normally distributed conditional on the available information set $I_{t-1}$ that contains both past of $X$ and $Y$:

$$X_t | I_{t-1} \sim \mathcal{N}(\mu + \beta X_{t-1}, \gamma + \delta Y_{t-1}^2).$$

Consequently, for $\tau \in (0,1)$, the $\tau$-th quantile of $X_t$ conditional on $I_{t-1}$ is given by:

$$Q^\tau(X_t | I_{t-1}) = \mu + \beta X_{t-1} + (\gamma + \delta Y_{t-1}^2)^{1/2} \Phi^{-1}(\tau),$$

(2)
where $\Phi^{-1}(\tau)$ is the $\tau$-th quantile of $N(0,1)$.

Equation (1) shows that $Y$ does not cause $X$ through its mean. However, from Equation (2) we observe that $Y$ does cause $X$ through its $\tau$-th quantile for $\tau \neq 0.5$. For example, for $\tau = 0.05$, $Y$ does cause $X$ through its 5-th quantile even if there is no causality through its mean. This example illustrates the case where the causality in terms of the mean does not exist; however, it does exist in quantiles. However, how can we measure the degree of this causality in quantile? Existing measures do not answer this question.

Generally speaking, the functional form of Granger causality in quantiles from $Y$ to $X$ may be unknown. In other words, the mean regression model can generally be defined as follows:

$$X_t = m(X_{t-1}, Y_{t-1}) + \sigma(X_{t-1}, Y_{t-1}) \epsilon_t,$$

where $\epsilon_t$ is normally (elliptically) distributed with mean zero and variance one. This implies that the $\tau$-th quantile of $X_t$ conditional on $I_{t-1}$ is given by:

$$Q^\tau(X_t | I_{t-1}) = m(X_{t-1}, Y_{t-1}) + \sigma(X_{t-1}, Y_{t-1}) \Phi^{-1}(\tau),$$

where the functional forms of $m(X_{t-1}, Y_{t-1})$ and $\sigma(X_{t-1}, Y_{t-1})$ are unknown. This shows the importance of developing measures of nonlinear Granger causality in quantiles and this can be achieved using nonparametric quantile regressions.

### 3 Framework

We consider two variables of interest $X$ and $Y$. For the simplicity of exposition, we assume that $X$ and $Y$ are univariate processes; however, in Section 8 we include a third variable $W$. In other words, in Section 8 we will still focus on the univariate quantiles; we will nevertheless extend the information set to include a third variable that can play the role of an auxiliary variable.

We wish to measure the Granger causality in quantiles between $X$ and $Y$. However, when it comes to Granger causality analysis, defining the information sets is crucial. Hereafter, we consider a sequence $I$ of “reference information sets” $I(t-1)$ such that:

$$I = \{I(t) : t \in \mathbb{Z}, t > \omega\} \text{ with } t < t' \Rightarrow I(t) \subseteq I(t') \text{ for all } t > \omega,$$

where $I(t)$ is an information set, $\omega \in \mathbb{Z} \cup \{-\infty\}$ represents a “starting point”, and $\mathbb{Z}$ is the set of integers. The “starting point” $\omega$ is typically equal to a finite initial date (such as $\omega = -1$, 0 or 1) or to $-\infty$; in the latter case $I(t)$ is defined for all $t \in \mathbb{Z}$. The information set $I(t)$ could correspond to a (possibly empty) set, whose elements represent the information available at any point of time, such as time independent variables (e.g., the constant in a regression model) and deterministic processes (e.g., deterministic trends).
We denote $X(\omega, t - 1)$ the information set spanned by $X_s$ for $\omega < s \leq t - 1$, and similarly for $Y(\omega, t - 1)$. That is, $X(\omega, t - 1)$ and $Y(\omega, t - 1)$ represent the information contained in the history of the variables $X$ and $Y$, respectively, up to time $t - 1$. Finally, the information sets obtained by “adding” $X(\omega, t - 1)$ to $I(t - 1)$ and $Y(\omega, t - 1)$ to $I_X(t - 1)$ are defined as

$$I_X(t - 1) = I(t - 1) + X(\omega, t - 1), \quad I_{XY}(t - 1) = I_X(t - 1) + Y(\omega, t - 1).$$

(4)

### 3.1 Characterization of Granger causality in quantiles

For any information set $B_{t-1}$, we denote $Q^r(X_t|B_{t-1})$ [resp. $Q^r(Y_t|B_{t-1})$] the best linear/nonlinear quantile forecast of $X_t$ [resp. $Y_t$] based on the information set $B_{t-1}$. Hereafter, the best forecast of $X_t$ [resp. $Y_t$] will be defined based on the following well-known quantile check loss function:

$$\rho_r(u) \equiv (\tau - 0.5)u + 0.5|u| = u(\tau - 1(u < 0)),$$

(5)

where $1(A)$ is an indicator function of an event $A$ and $\tau$ is the quantile of interest. In other words, the best quantile forecasts of $X_t$ and $Y_t$ based on the information set $B_{t-1}$ are

$$Q^r(X_t|B_{t-1}) = \arg\min_\theta E[\rho_r(X_t - \theta) | B_{t-1}],
\quad Q^r(Y_t|B_{t-1}) = \arg\min_\theta E[\rho_r(Y_t - \theta) | B_{t-1}].$$

Using the above notations and based on the expectations of quantile check loss functions the following definition provides a characterization of Granger non-causality in quantiles between $X$ and $Y$.

**Definition 1** [Characterization of Non-Causality in Quantiles]. For $\tau \in (0, 1)$, $Y$ does not cause $X$ through its $\tau$-th quantile given $I$, iff

$$E[\rho_r(X_t - Q^r(X_t|I_X(t-1)))] = E[\rho_r(X_t - Q^r(X_t|I_{XY}(t-1)))] \quad \forall t > \omega,$$

where the information sets $I_X(t-1)$ and $I_{XY}(t-1)$ are defined in (4).

Similarly, for $\tau \in (0, 1)$, $X$ does not cause $Y$ through its $\tau$-th quantile given $I$, iff

$$E[\rho_r(Y_t - Q^r(Y_t|I_Y(t-1)))] = E[\rho_r(Y_t - Q^r(Y_t|I_{XY}(t-1)))] \quad \forall t > \omega,$$

where the information set $I_{XY}(t-1)$ is defined in (4) and $I_Y(t-1) = I(t-1) + Y(\omega, t-1)$.

Definition (1) means that $Y$ causes $X$ [resp. $X$ causes $Y$] if the past of $Y$ [resp. $X$] improves the forecast of the $\tau$-th quantile of $X_t$ [resp. $Y_t$] based on the information in $I_Y(t-1)$ [resp. $I_X(t-1)$]. Next, we provide the expressions of the measures of Granger causality in quantiles.
3.2 Causality measures

Using the characterization of Granger non-causality in Definition (1) and based on the following idea, we introduce measures of Granger causality in quantiles. For \( \tau \in (0, 1) \), we state that "\( Y \) causes \( X \) through its \( \tau \)-th quantile" if

\[
E[\rho_\tau(X_t - Q^\tau(X_t | I_X(t-1)))] > E[\rho_\tau(X_t - Q^\tau(X_t | I_{XY}(t-1)))].
\]   \( 6 \)

Similarly, "\( X \) causes \( Y \) through its \( \tau \)-th quantile" if

\[
E[\rho_\tau(Y_t - Q^\tau(Y_t | I_Y(t-1)))] > E[\rho_\tau(Y_t - Q^\tau(Y_t | I_{XY}(t-1)))].
\]   \( 7 \)

Consequently, measuring the difference between the two loss functions on the left and right-hand side of the inequality (6) [resp. (7)] is the same as measuring the strength of causality in the \( \tau \)-th quantile from \( Y \) [resp. \( X \)] to \( X \) [resp. \( Y \)].

The Granger causality measures that we propose here are suitable functions of the “distance” between the loss functions on the left and right-hand side of the inequalities in (6) and (7). These measures are defined using similar measure functions as in Geweke (1982, 1984) as well as Dufour and Taamouti (2010). Important properties of these measure functions are that they are non-negative and cancel only when there is no causality. Specifically, we propose the following causality measures where by convention \( \ln(0/0) = 0 \) and \( \ln(x/0) = +\infty \) for \( x > 0 \).

**Definition 2** [Quantile Causality Measures]. For \( \tau \in (0, 1) \), the function

\[
C_\tau(Y \rightarrow X | I) = \ln \left[ \frac{E[\rho_\tau(X_t - Q^\tau(X_t | I_X(t-1)))]}{E[\rho_\tau(X_t - Q^\tau(X_t | I_{XY}(t-1)))]} \right]
\]   \( 8 \)

defines the \( \tau \)-th quantile causality measure from \( Y \) to \( X \), given \( I \). Similarly, the function

\[
C_\tau(X \rightarrow Y | I) = \ln \left[ \frac{E[\rho_\tau(Y_t - Q^\tau(Y_t | I_Y(t-1)))]}{E[\rho_\tau(Y_t - Q^\tau(Y_t | I_{XY}(t-1)))]} \right]
\]

defines the \( \tau \)-th quantile causality measure from \( X \) to \( Y \), given \( I \).

\( C_\tau(Y \rightarrow X | I) \) [resp. \( C_\tau(X \rightarrow Y | I) \)] measures the degree of causal effect from \( Y \) [resp. \( X \)] to the \( \tau \)-th quantile of \( X \) [resp. \( Y \)] given the past of \( Y \) [resp. \( X \)]. With relation to predictability, they can be viewed as measures of the amount of information brought by the past of \( Y \) [resp. \( X \)], which can in turn improve the forecast of the \( \tau \)-th quantile of \( X_t \) [resp. of \( Y_t \)].

4 Nonparametric causality measures

Let \( \{(X_t, Y_t) \in \mathbb{R} \times \mathbb{R} = \mathbb{R}^2, \ t = 0, ..., T\} \) be a sample of strictly stationary stochastic process in \( \mathbb{R}^2 \). Denote \( X_{t-1} = (X_{t-1}, ..., X_{t-d_1})' \) and \( Y_{t-1} = (Y_{t-1}, ..., Y_{t-d_2})' \) for some fixed known integers \( d_1 \geq 1 \) and \( d_2 \geq 1 \). To avoid useless repetitions, we treat only the causality from \( Y \) to \( X \) in the following section.
We assume that the following nonparametric unconstrained quantile regression hold, i.e. for a fixed quantile \( \tau \), for \( 0 < \tau < 1 \),

\[
X_t = m_{1\tau}(Z_{t-1}) + \varepsilon_{1t},
\]

where \( Z_{t-1} = (X_{t-1}', Y_{t-1}')' \) is a \( d + d_1 + d_2 \) dimensional random vector, \( m_{1\tau}(Z_{t-1}) = Q_{\tau}(X_t | Z_{t-1}) \), and \( \varepsilon_{1t} = X_t - Q_{\tau}(X_t | Z_{t-1}) \). Thus, \( \varepsilon_{1t} \) is an error term with its \( \tau \)-th conditional quantile given \( Z_{t-1} \) equal to zero, i.e. \( \Pr(\varepsilon_{1t} \leq 0 | Z_{t-1} = \hat{z}) = \tau \) for almost all \( \hat{z} \).

It is well established in the quantile regression literature that the (unique) conditional quantile function \( m_{1\tau}(Z_{t-1}) \) solves the following optimization problem:

\[
\min_{\theta} E[\rho_{\tau}(X_t - \theta)|Z_{t-1}],
\]

where \( \rho_{\tau}(u) \) is the quantile check loss function given in (5). Therefore, we can define the following corresponding expectation of check loss function

\[
E[\rho_{\tau}(\varepsilon_{1t}) | I_{t-1}] = E[\rho_{\tau}(X_t - m_{1\tau}(Z_{t-1}))].
\]

To quantify the degree of Granger causality in quantile from \( Y \) to \( X \), we further consider the following nonparametric constrained quantile regression:

\[
X_t = m_{1\tau}(X_{t-1}) + \tau_{1t},
\]

where \( m_{1\tau}(X_{t-1}) = \arg\min_{\theta} E[\rho_{\tau}(X_t - \theta)|X_{t-1}] \) is the unique conditional \( \tau \)-th quantile of \( X_t \) given \( X_{t-1} \).

Next, we define the nonparametric regression-based measures of Granger causality in quantiles from \( Y \) to \( X \).

**Proposition 1** Under the quantile regressions (9) and (10), for non-negative weighting function \( w(\cdot) \) and a fixed quantile \( \tau \), for \( 0 < \tau < 1 \), the function

\[
C_{\tau}(Y \rightarrow X | I) = \ln \left[ \frac{E[\rho_{\tau}(X_t - m_{1\tau}(X_{t-1}))w(Z_{t-1})]}{E[\rho_{\tau}(X_t - m_{1\tau}(Z_{t-1}))w(Z_{t-1})]} \right]
\]

is the \( \tau \)-th quantile causality measure from \( Y \) to \( X \), given \( I \).

The inclusion of non-negative weighting function \( w(\cdot) \) in the expression of measure of Granger causality in quantile is to avoid highly uncertain estimation of these measures especially in regions with sparse or noisy data. In practice, \( w(\cdot) \) will typically take the value that is one in the center of the support of \( Z \) and zero near the boundary. The introduction of the weight \( w(\cdot) \) also permits the users to focus their analysis on a given range of interest of the variables.

Further, notice that when \( m_{1\tau}(Z_{t-1}) = m_{1\tau}(X_{t-1}) \) with probability one; in other words, there is no causality from \( Y \) to \( X \) through its \( \tau \)-th quantile, the measure function is \( C_{\tau}(Y \rightarrow X | I) = 0 \). It is worthwhile to remark that our proposed measure \( C_{\tau}(Y \rightarrow X | I) \) is local since for different quantiles there may exhibit different degrees of causality.
5 Estimation

In this section, we provide a consistent nonparametric estimator for the above measures of Granger causality in quantiles. We have shown (refer to Section 4) that the causality measure can be expressed in terms of restricted and unrestricted conditional expectations of quantile check loss functions. Thus, this measure can be estimated by replacing the unknown expectations of check loss functions by their nonparametric estimates from a finite sample. In particular, we need nonparametric estimates for the following restricted and unrestricted quantile regression errors: \( X_t - m_{1\tau}(X_{t-1}) \) and \( X_t - m_{1\tau}(Z_{t-1}) \). Due to its well-known advantages, we propose to use the local polynomial approach to construct our nonparametric estimates as discussed in Fan and Gijbels (1996). Herein, we focus on the estimation of measure of Granger causality in quantiles from \( Y \) to \( X \), \( C_{\tau}(Y \rightarrow X \mid I) \). Similarly, we can propose an estimator for the measure of Granger causality in quantiles from \( X \) to \( Y \), \( C_{\tau}(X \rightarrow Y \mid I) \). Further, for simplicity of exposition and to economize space, hereafter, we omit the information set \( I \) in the notations of subsequent Granger causality measures and their corresponding estimates.

First of all, assume that the constrained [resp. unconstrained] \( \tau \)-th conditional quantile function \( m_{1\tau}(z) \) [resp. \( m_{1\tau}(z) \)] is differentiable continuously at \( z = (x_1, \ldots, x_{d_1})' \) [resp. \( z = (x', y')' \), with \( y = (y_1, \ldots, y_{d_2})' \)] up to order \( p + 1 \) [resp. \( q + 1 \)]. Then, the multivariate \( p \)-th order local polynomial approximation of the constrained \( \tau \)-th conditional quantile function \( m_{1\tau}(g) \), for any \( g \) close to \( z \), is given by

\[
m_{1\tau}(g) \approx \sum_{0 \leq |\xi| \leq p} \frac{1}{r!} D^r m_{1\tau}(x)(g - x)^{r},
\]

where \( r = (r_1, \ldots, r_{d_1}) \), \( |r| = \sum_{i=1}^{d_1} r_i \), \( r' = r_1! \times \cdots r_{d_1}! \), and

\[
D^r m_{1\tau}(x) = \frac{\partial^{|\xi|} m_{1\tau}(x)}{\partial x_1^{r_1} \cdots \partial x_{d_1}^{r_{d_1}}}
\]

for \( x^{r} = x_1^{r_1} \times \cdots \times x_{d_1}^{r_{d_1}} \) and \( \sum_{0 \leq |\xi| \leq p} = \sum_{j=0}^{p} \sum_{r_1=0}^{j} \cdots \sum_{r_{d_1}=0}^{j} \sum_{r_1+\cdots+r_{d_1}=j} \).

Now, let \( K(\xi) \) be a multivariate product density function on \( \mathbb{R}^{d_1} \) and \( h_1 \equiv h_1T \in \mathbb{R}^{+} \) a bandwidth parameter converging to zero at appropriate rates specified in Assumption A.9 of Appendix A.1. Using the sample \( \{(X_t, Y_t)\}_{t=0}^{T} \), we consider minimizing the following quantity with respect to \( \beta_{\tau} \), \( 0 \leq |\xi| \leq p \), to derive the constrained estimator \( \hat{m}_{1\tau}(z) \) evaluated at the data point \( z = X_{t-1} \):

\[
\min_{\beta_{\tau}} \sum_{s=1, s\neq t}^{T} K_{h_1}(X_{s-1} - X_{t-1}) \rho_{\tau} \left( X_s - \sum_{0 \leq |\xi| \leq p} \beta_{\tau}(X_{s-1} - X_{t-1})^{\xi} \right),
\]

(12)

where \( K_{h_1}(\xi) = K(\xi/h_1)/h_{d_1}^{d_1} \). Let \( \hat{\beta}_{\tau}(X_{t-1}) \), for \( 0 \leq |\xi| \leq p \), be the minimizer of the above optimization problem. The leave-one-out estimator for the \( \tau \)-th constrained conditional quantile function \( m_{1\tau}(x) \) and its
partial derivatives $D^2 m_{1,\tau}(\bar{x})$ evaluated at $\bar{x} = X_{t-1}$ are then given by

$$\hat{m}_{t,1\tau}(X_{t-1}) = \hat{\beta}_0 \quad \text{and} \quad \hat{D}^2 m_{t,1\tau}(X_{t-1}) = t' \hat{\beta}_2,$$

for $1 \leq |r| \leq p$.

Similarly, we denote the multivariate $q$-th order local polynomial leave-one-out estimator of the unconstrained $\tau$-th conditional quantile function $m_{1,\tau}(\bar{z})$ and its derivatives $D^2 m_{1,\tau}(\bar{z})$ evaluated at the data point $\bar{z} = Z_{t-1}$ by $\hat{m}_{t,1,\tau}(Z_{t-1})$ and $\hat{D}^2 m_{t,1,\tau}(Z_{t-1})$, for $1 \leq |r| \leq q$, respectively. Therefore, based on the above local polynomial leave-one-out estimators $\hat{m}_{t,1,\tau}(X_{t-1})$ and $\hat{m}_{t,1,\tau}(Z_{t-1})$, we propose

$$C_\tau (Y \to X) = \ln \left( \frac{T^{-1} \sum_{t=1}^{T} \rho_\tau \left( X_t - \hat{m}_{t,1,\tau}(X_{t-1}) \right) w(Z_{t-1})}{T^{-1} \sum_{t=1}^{T} \rho_\tau \left( X_t - \hat{m}_{t,1,\tau}(Z_{t-1}) \right) w(Z_{t-1})} \right)$$

(13)

as a suitable nonparametric estimator of the causality measure $C_\tau (Y \to X)$ in (11). As we will show in the proof of Theorem 2, using leave-one-out estimators helps to reduce the bias in estimating the measure $C_\tau (Y \to X)$. The consistency of the estimator in (13) will be established for any continuous weight function $w(\cdot)$ defined on a compact and non-empty interior support. Finally, the nonparametric estimator of the measure of Granger causality from $X$ to $Y$ through its $\tau$-th quantile can be obtained following the same steps. Hereafter, we will omit the subscript “$-t$” of the leave-one-out estimators $\hat{m}_{t,1,\tau}(X_{t-1})$ and $\hat{m}_{t,1,\tau}(Z_{t-1})$ in the expression (13) to minimize the notation.

6 Asymptotic properties

This section aims to establish the asymptotic properties of nonparametric estimator $C_\tau (Y \to X)$ defined in Equation (13). Before proceeding with this, we need to introduce some notations to facilitate the study of local polynomial estimators. Following Kong et al. (2010), let $N_i = \binom{i + d_1 - 1}{d_1 - 1}$ be the number of distinct $d_1$-tuples $\tau$ with $\tau = i$. Arrange these $N_i$ $d_1$-tuples as a sequence in a lexicographical order, with the highest priority given to the last position so that $(0, \ldots, 0, i)$ is the first element in the sequence and $(i, 0, \ldots, 0)$ is the last element. Let $\pi_i$ denote the 1-to-1 mapping defined by $\pi_i(1) = (0, \ldots, 0, i), \ldots, \pi_{N_i} = (i, 0, \ldots, 0)$. Furthermore, for each $i = 1, \ldots, p$, define a $N_i \times 1$ vector $\mu_i(\bar{x})$ with its $k$-th element given by $\bar{x}^{\pi_i(k)}$, and write $\mu(\bar{x}) = (1, \mu_1(\bar{x})', \ldots, \mu_p(\bar{x})')'$, which is a column vector of length $N = \sum_{i=0}^{p} N_i$. Similarly, define vectors $\beta_p(\bar{x})$ and $\hat{\beta}$ through the same lexicographical arrangement of $D^2 m_{1,\tau}(\bar{x})$ and $\hat{\beta}_2$ in Equation (12) for $0 \leq |r| \leq p$. Thus, Equation (12) can be rewritten as

$$\sum_{s=1, s \neq t}^{T} K_{h_1} (X_{s-1} - X_{t-1}) \rho_\tau \left( X_s - \mu \left( X_{s-1} - X_{t-1} \right)' \hat{\beta} \right).$$

(14)

Now, let us denote the minimizer of equation (14) by $\hat{\beta}_T(X_{t-1})$, and let $\hat{\beta}_p(X_{t-1}) = W_p \hat{\beta}_T(X_{t-1})$, where $W_p$ is a diagonal matrix with diagonal entries that are equal to the lexicographical arrangement of $r'$, for
0 ≤ |r| ≤ p. In addition, let \( \varphi(u) = \tau 1(u \geq 0) + (\tau - 1)1(u < 0) \) be the piecewise constant derivative of the check loss function \( \rho_r(u) \) given in (5). Define \( G(\theta, \underline{x}) = E[\varphi(X_t - \theta) | X_{t-1} = \underline{x}] \) and \( g(\underline{x}) = \partial G(\theta, \underline{x}) / \partial \theta \). Then, it holds true that \( g(\underline{x}) = -f_{\tau_1}X(0 | \underline{x}) \), where \( f_{\tau_1}X(0 | \underline{x}) \) is the conditional probability density function of the constrained quantile error \( \varepsilon_{1t} = X_t - \hat{m}_1r(X_{t-1}) \) given \( X_{t-1} = \underline{x} \). Let \( \nu_{1} = \int K(u)u^k du \) and define \( \nu_{T;1} = \int K(u)u^k g(x + h_1 u) f_X(x + h_1 u) du \), where \( f_X(\cdot) \) is the marginal probability density function of \( X_{t-1} \).

Finally, for \( 0 \leq j, k \leq p \), let \( S_{j,k} \) and \( S_{T,j,k}(\underline{x}) \) be two \( N_j \times N_k \) matrices with their \((l, m)\) elements, respectively, given by

\[
[S_{j,k}]_{l,m} = \nu_{\pi_j(l) + \pi_k(m)} \quad \text{and} \quad [S_{T,j,k}(\underline{x})]_{l,m} = \nu_{T,\pi_j(l) + \pi_k(m)}(\underline{x}).
\]

Using the above notations, we now define the \( N \times N \) matrices \( S_p \) and \( S_{T,p}(\underline{x}) \):

\[
S_p = \begin{bmatrix}
S_{0,0} & S_{0,1} & \cdots & S_{0,p} \\
S_{1,0} & S_{1,1} & \cdots & S_{1,p} \\
\vdots & \vdots & \ddots & \vdots \\
S_{p,0} & S_{p,1} & \cdots & S_{p,p}
\end{bmatrix}, \\
S_{T,p}(\underline{x}) = \begin{bmatrix}
S_{T,0,0}(\underline{x}) & S_{T,0,1}(\underline{x}) & \cdots & S_{T,0,p}(\underline{x}) \\
S_{T,1,0}(\underline{x}) & S_{T,1,1}(\underline{x}) & \cdots & S_{T,1,p}(\underline{x}) \\
\vdots & \vdots & \ddots & \vdots \\
S_{T,p,0}(\underline{x}) & S_{T,p,1}(\underline{x}) & \cdots & S_{T,p,p}(\underline{x})
\end{bmatrix}.
\]

Further, for \( |S_p| \neq 0 \), define

\[
\beta_T^p(X_{t-1}) = -\frac{1}{Th_{1}^{4/3}}W_p S_{T,p}^{-1}(\underline{x}) H_T^{-1}\sum_{s=1, s \neq t}^T K_h(X_{s-1} - X_{t-1})\varphi(X_s - \mu(X_{s-1} - X_{t-1}) W_p^{-1} \beta_p(X_{t-1})) \mu(X_{s-1} - X_{t-1}),
\]

where \( H_T \) is a diagonal matrix with diagonal entries \( h_{1}^{4/3} \), for \( 0 \leq |r| \leq p \), in the aforementioned lexicographical order. The quantity \( \beta_T^p(X_{t-1}) \) is the leading term in the Bahadur representation of \( \hat{\beta}_p(X_{t-1}) - \beta_p(X_{t-1}) \), which is the sum of a bias term \( E_s[\beta_T^p(X_{t-1})] \) (with \( E_s \) denoting expectation with respect to \( s \)) and a stochastic term \( \beta_T^p(X_{t-1}) - E_s[\beta_T^p(X_{t-1})] \); for more details, among other studies, refer to Kong et al. (2010), Guerre and Sabbah (2012), and Noh et al. (2013).

The \( q \)-th order local polynomial leave-one-out estimator for the unconstrained conditional quantile function \( m_{1r}(Z_{t-1}) \) using a second bandwidth \( h_2 \), denoted by \( \hat{m}_{1r}(Z_{t-1}) \), can accordingly be defined as above for \( \hat{m}_{1r}(X_{t-1}) \). Therefore, we omit the steps for constructing \( \hat{m}_{1r}(Z_{t-1}) \).

### 6.1 Bahadur representation

In this subsection, we establish a Bahadur type representation for the nonparametric estimator in Equation (13). This representation will be used to deduce the most basic property, which the latter estimator should have consistency. To derive the Bahadur’s representation of \( C_T(X \rightarrow Y) \), some regularity assumptions are needed. Therefore, we consider a set of standard assumptions that have been widely used in the literature on nonparametric estimation and inference; refer to, for example, Kong et al. (2010) and Noh et al. (2013), among others. For simplicity of exposition, we relegate all these assumptions to Appendix A.1. The following
Theorem 1 Let \( d = d_1 + d_2 \). Suppose Assumptions A.1-A.9 in Appendix A.1 hold, \( p > d_1/2 - 1, h_1 = O(T^{-\kappa_1}) \) with \( 1/(2p + 2 + d_1) < \kappa_1 < 1/(2d_1) \), \( q > d/2 - 1, \) and \( h_2 = O(T^{-\kappa_2}) \) with \( 1/(2p + 2 + d) < \kappa_2 < 1/(2d) \). Then, for each given quantile \( \tau \in (0,1) \), we have

\[
\sqrt{T} \left( C_\tau \left( \hat{Y} \to X \right) - C_\tau \left( Y \to X \right) \right) = (1 + C_\tau \left( Y \to X \right)) \frac{1}{\sqrt{T}} \sum_{t=1}^{T} (e_t - u_t) + o_p(1),
\]

where

\[
e_t = \rho_\tau \left( X_t - m_{1T} (X_{t-1}) \right) w (Z_{t-1}) - E \left[ \rho_\tau \left( X_t - m_{1T} (X_{t-1}) \right) w (Z_{t-1}) \right],
\]

and

\[
u_t = \rho_\tau \left( X_t - m_{1T} (Z_{t-1}) \right) w (Z_{t-1}) - E \left[ \rho_\tau \left( X_t - m_{1T} (Z_{t-1}) \right) w (Z_{t-1}) \right].
\]

Note that the conditions \( p > d_1/2 - 1 \) and \( q > d/2 - 1 \) are needed to obtain the asymptotic representations of the empirical analogue of the check loss functions involving \( \hat{m}_{1T} (\cdot) \) and \( \hat{m}_{1T} (\cdot) \), respectively; refer to Lemmas 3 and 4 in Appendix B. They imply that the orders \( p \) and \( q \) of the local polynomial approximations of \( \hat{m}_{1T} (\cdot) \) and \( m_{1T} (\cdot) \) should increase as the dimensions \( d_1 \) and \( d \) of \( X_{t-1} \) and \( Z_{t-1} \) increase, respectively.

One immediate implication of Theorem 1 is that the estimator \( C_\tau \left( \hat{Y} \to X \right) \) in (13) is consistent. Thus, the following proposition can be straightforwardly deduced from the above Bahadur’s representation of \( C_\tau \left( \hat{Y} \to X \right) \), therefore its proof has been omitted.

Proposition 2 Under Assumptions A.1-A.9 in Appendix A.1, for each given quantile \( \tau \in (0,1) \), the nonparametric estimator \( C_\tau \left( \hat{Y} \to X \right) \) in (13) converges in probability to the true Granger causality measure \( C_\tau \left( Y \to X \right) \) in (11).

Besides the consistency property, the Bahadur representation implies \( \sqrt{T} \left( C_\tau \left( \hat{Y} \to X \right) - C_\tau \left( Y \to X \right) \right) \) is asymptotically normal with mean zero and variance \( \sigma_{1 T}^2 := (1 + C_\tau \left( Y \to X \right))^2 \Sigma_T \), where

\[
\Sigma_T = \lim_{T \to \infty} T^{-1} \text{Var} \left( \sum_{t=1}^{T} (e_t - u_t) \right) = \text{Var} (e_1 - u_1) + 2 \sum_{t>1} \text{Cov} (e_1 - u_1, e_t - u_t).
\]

Specifically, the asymptotic normality of \( C_\tau \left( \hat{Y} \to X \right) \) can be established by applying the central limit theorem to the strong mixing process \( \{(e_t - u_t)\}_{t=1}^{T} \); refer to, for example, Theorem 2.21 in Fan and Yao (2003). One direct application of the latter is the construction of confidence intervals for the causality measure \( C_\tau(Y \to X) \). However, recall that by construction \( C_\tau(Y \to X) \) is non-negative and it is zero if and only if there is no causality from \( Y \) to \( X \) through its \( \tau \)-th quantile. It is immediate to observe that when \( C_\tau(Y \to X) = 0 \), the asymptotic variance \( \sigma_{1 T}^2 \), given before, degenerates to zero. This means that
the asymptotic normality result, which can be obtained using Theorem 1, is also a degenerate distribution and is meaningless except the consistency of $C_r(Y \to X)$ to zero. Thus, unlike the cases when the degree of Granger causality in quantiles is important (i.e. value of the causality measure is non-zero or large), we should herein investigate the next leading term in the previous Bahadur expansion in order to get a non-degenerated distributional result. We will study this important case in detail in the next section.

6.2 Inference

The causality measures, which we introduced in the previous sections, can be used to test for Granger non-causality in quantiles between $X$ and $Y$. If there is no causality from $Y$ to $X$ through its $\tau$-th quantile, then the restricted and unrestricted expectations of quantile check loss functions will be equal: $E[p_r(X_t - \overline{m}_{1\tau}(Z_{t-1}))] = E[p_r(X_t - m_{1\tau}(Z_{t-1}))].$ Hereafter, we will use the latter argument to test the null hypothesis of Granger non-causality in certain quantiles. In other words, for a pre-specified quantile $\tau$, for $0 < \tau < 1$, we are interested in testing the null hypothesis

$$H_0 : C_r(Y \to X) = 0$$

against the alternative hypothesis

$$H_1 : C_r(Y \to X) > 0.$$  

As we had discussed at the end of the previous subsection, under $H_0$, the Bahadur representation in Theorem 1 tells us nothing about the asymptotic distribution of $C_r(Y \to X)$. Therefore, to test $H_0$ against $H_1$ we need to derive a non-degenerated distribution of $C_r(Y \to X)$ when $C_r(Y \to X) = 0$ is true. Using the theory for $U$-statistics, the following theorem provides non-degenerate asymptotic normality of the nonparametric estimator $C_r(Y \to X)$ at a given quantile $\tau$, for $0 < \tau < 1$ [refer to the proof of Theorem 2 in Appendix A.2]. Again, here, in this study, we focus only on Granger causality from $Y$ to $X$, however, a similar result can be obtained for Granger causality from $X$ to $Y$.

**Theorem 2** Let $d = d_1 + d_2$. Suppose Assumptions A.1-A.9 in Appendix A.1 hold, $p > d_1/2 - 1$ and $h_1 = O(T^{-\kappa_1})$ with $1/(2p+2+d_1) < \kappa_1 < 1/(2d_1)$, and $q > d/2 - 1$ and $h_2 = O(T^{-\kappa_2})$ with $1/(2q+2+d) < \kappa_2 < 1/(2d)$. Then, under the null hypothesis $H_0$ in (15), we have

$$Th_2^{d/2}C_r(Y \to X) \overset{d}{\to} N\left(0, \sigma_{0r}^2\right),$$

where

$$\sigma_{0r}^2 = \frac{2\tau^2 (1-\tau)^2}{C_r^2} \int K^2(u) du \int \frac{w^2(z)}{f_{\varepsilon_{1\tau}}(0|\varepsilon)} d\varepsilon,$$

with $C_r = E\left[p_r(X_t - m_{1\tau}(Z_{t-1})) w(Z_{t-1})\right]$, $f_{\varepsilon_{1\tau}}(0|\varepsilon)$ is the conditional density of $\varepsilon_{1\tau} = X_t - m_{1\tau}(Z_{t-1})$ given $Z_{t-1} = \varepsilon$ evaluated at $\varepsilon_{1\tau} = 0$. 

To implement the test in practice, we require a consistent estimator of \( \sigma_{0r}^2 \). In this study, we propose to replace \( \sigma_{0r}^2 \) by the following estimator:

\[
\hat{\sigma}_{0r}^2 = \frac{2\tau^2 (1 - \tau)^2}{C_r^2} \frac{1}{T(T - 1)} \sum_{t=1}^{T} \sum_{s=1, s \neq t}^{T} w_2(Z_{t-1}) \frac{\hat{f}_{\varepsilon}(0)dz_{t-1} f_{\varepsilon}(Z_{t-1})}{h_2} K^2 \left( \frac{Z_{t-1} - Z_{s-1}}{h_2} \right),
\]

where \( \hat{f}_{\varepsilon}(0)dz_{t-1} \) and \( f_{\varepsilon}(Z_{t-1}) \) are usual nonparametric kernel estimators of the (conditional) probability density functions \( f_{\varepsilon}(0)dz_{t-1} \) and \( f_{\varepsilon}(Z_{t-1}) \), respectively, and

\[
\hat{C}_r = \frac{1}{T} \sum_{t=1}^{T} \rho_\tau(X_t - \hat{m}_1(Z_{t-1}))w(Z_{t-1})
\]

is a consistent estimator of \( C_r \).\(^2\) We now define the following feasible statistic test for testing \( H_0 \) against \( H_1 \):

\[
\Gamma_\tau := \frac{T_{\hat{h}_2}^{d/2} C_\tau (\bar{Y} \rightarrow X)}{\hat{\sigma}_{0r}}.
\]

Under \( H_0 \), Theorem 2 implies that the test statistic \( \Gamma_\tau \) is asymptotically pivotal and asymptotically distributed as \( \mathcal{N}(0, 1) \). This result forms the basis for the following one-sided asymptotic test for \( H_0 \): for a given significance level \( \alpha \), we reject the null \( H_0 \) if \( \Gamma_\tau > z_\alpha \), where \( z_\alpha \) is the one-sided critical value, i.e. the upper \( \alpha \)-th percentile from the standard normal distribution.

The following proposition establishes the consistency of the above test for the fixed alternative (16). It shows that the test statistic \( \hat{\Gamma}_\tau = T_{\hat{h}_2}^{d/2} C_\tau (\bar{Y} \rightarrow X)/\hat{\sigma}_{0r} \) diverges to infinity under the alternative hypothesis \( H_1 \) [refer to the proof of Proposition 3 in Appendix A.2].

**Proposition 3** Let \( d = d_1 + d_2 \). Suppose Assumptions A.1-A.9 in Appendix A.1 hold, \( p > d_1/2 - 1 \) and \( h_1 = O(T^{-\kappa_1}) \) with \( 1/(2p + 2 + d_1) < \kappa_1 < 1/(2d_1) \), and \( q > d/2 - 1 \) and \( h_2 = O(T^{-\kappa_2}) \) with \( 1/(2q + 2 + d) < \kappa_2 < 1/(2d) \). Then, under the alternative hypothesis of causality in (16), we have

\[
Pr \left\{ T_{\hat{h}_2}^{d/2} C_\tau (\bar{Y} \rightarrow X)/\hat{\sigma}_{0r} > B_T \right\} \rightarrow 1,
\]

for any non-stochastic sequence \( B_T = o \left( T_{\hat{h}_2}^{d/2} \right) \).

We also examine the asymptotic power of the test for detecting local departures, which converge to the null hypothesis (15) at a suitable rate. Specifically, we introduce a sequence of Pitman-type local alternatives of the following form:

\[
H_1 (\delta_T) : m_{1i}(z) = \bar{m}_{1i}(\bar{z}) + \delta_T \Delta_T (\bar{z}),
\]

where \( \delta_T \) might depend on \( \tau \) and \( \delta_T \rightarrow 0 \) as \( T \rightarrow \infty \), and \( \Delta_T (\bar{z}) \) is a non-constant continuous function in \( \bar{z} \); this indicates how large the deviation of \( m_{1i}(\bar{z}) \) is from \( \bar{m}_{1i}(\bar{z}) \). Equivalently, \( \Delta_T (\bar{z}) \) indicates how large

\(^2\)The proof of the consistency of the estimator \( \hat{\sigma}_{0r}^2 \) to \( \sigma_{0r}^2 \) can be found in the proof of Theorem 2 in Appendix A.2.
the deviation of the measure \( C_\tau(Y \rightarrow X) \) is from zero. Further, we define the following term:

\[
\gamma = C_\tau^{-1} \lim_{T \to \infty} E \left[ \Delta^2_T(Z_{t-1}) w(Z_{t-1}) f_{t-1|Z|0} \right].
\] (20)

We also assume \( \Delta_T(z) \) is a function that satisfies \( \gamma \neq 0 \). The following proposition states that our test has a non-trivial asymptotic local power against the sequence of Pitman local alternatives defined in (19), which converges to the null at the rate \( T^{-1/2} h_2^{-d/4} \) [refer to the proof of Proposition 4 in Appendix A.2].

**Proposition 4** Let \( d = d_1 + d_2 \). Suppose Assumptions A.1-A.9 in Appendix A.1 hold, \( p > d_1/2 - 1 \) and \( h_1 = O(T^{-\kappa_1}) \) with \( 1/(2p + 1) \) < \( \kappa_1 \) < \( 1/(2d_1) \), and \( q > d_2 - 1 \) and \( h_2 = O(T^{-\kappa_2}) \) with \( 1/(2q + 2 + d) \) < \( \kappa_2 \) < \( 1/(2d) \). Then, under the local alternatives \( H_1(\delta_T) \) in (19) with \( \delta_T = \left( T h_2^{d/2} \right)^{-1/2} \), we have

\[
Th_2^{d/2} C_\tau(Y \rightarrow X) \overset{d}{\rightarrow} N(\gamma, \sigma^2_{0\tau}),
\]

where \( \sigma^2_{0\tau} \) is defined in Theorem 2 and \( \gamma \) is defined in (20).

Finally, we observe that the above test can be generalized to build test statistics for testing Granger non-causality at a certain range of quantiles. In other words, for a set \( [a; b] \subset (0, 1) \), we wish to test the null hypothesis

\[
H_0 : C_\tau(Y \rightarrow X) = 0, \text{ for all } \tau \in [a, b].
\] (21)

Another closely related and equally important problem would be to test the following null hypothesis:

\[
H_0 : C_\tau(Y \rightarrow X) = 0, \text{ for all } \tau \in (0, 1),
\] (22)

which is equivalent to testing the conditional independence (CI) assumption between \( X_t \) and \( Y_{t-1} \) given \( X_{t-1} \), i.e.

\[
X_t \perp Y_{t-1} | X_{t-1}.
\]

refer to, for example, Bouezmarni et al. (2012) for a recent review of testing CI. Under our framework, the null hypotheses in (21) and (22) can be tested using supremum-type test statistics such as

\[
\sup_{\tau \in [a,b]} \left\{ T h_2^{d/2} C_\tau(Y \rightarrow X) \right\} \quad \text{and} \quad \sup_{\tau \in (0,1)} \left\{ T h_2^{d/2} C_\tau(Y \rightarrow X) \right\},
\]

respectively. The investigation of the asymptotic null distributions and power properties of such global-type test statistics are technically involved and will require considerable efforts; hence, we leave it for future studies.

### 7 Bootstrap

The result in Theorem 2 is valid only asymptotically. The asymptotic normal distribution might not work well in the finite samples and our unreported simulations using asymptotic critical values also confirm this observation. Particularly, for high dimensional random variables the asymptotic test is subject to huge
size distortion because of possible finite-sample bias in the nonparametric estimation due to the curse of dimensionality. One way to improve the size performance of the asymptotic test is to use the smoothed local bootstrap introduced in Paparoditis and Politis (2000). One major advantage of smoothed local bootstrap procedure is that it can preserve the unknown dependence structure in the data; thus, it can “mimic” adequately the finite-sample distribution of our test statistic. Thus, in this section, we propose a bootstrap-based procedure to improve the performance of our test in Theorem 2 in finite samples.

In the sequel, $X \sim f_X$ means that the random variable $X$ is generated from a density function $f_X$. Let $L_1$, $L_2$ and $L_3$ be three kernels and $h^*$ be a bandwidth parameter. Hereafter, we discuss the implementation of the test based on local smoothed bootstrap. It is easy to implement in the following four steps:

1. We draw a bootstrapped sample $\{(X_t^*, Y_t^*)\}_{t=1}^T$. To do so, we first draw $X_{t-1}^*$ from its nonparametric (kernel) marginal probability density

$$X_{t-1}^* \sim \frac{1}{Th^*d_1} \sum_{s=1}^T L_1 \left( \frac{X_{s-1} - x}{h^*} \right),$$

then conditional on $X_{t-1}^*$, we draw $X_t^*$ and $Y_{t-1}^*$ independently from the following two nonparametric (kernel) conditional probability densities:

$$X_t^* \sim \frac{1}{h^*d_2} \sum_{s=1}^T L_1 \left( \frac{X_{s-1} - X_{t-1}^*}{h^*} \right) L_2 \left( \frac{X_s - x}{h^*} \right) / \sum_{s=1}^T L_1 \left( \frac{X_{s-1} - X_{t-1}^*}{h^*} \right)$$

and

$$Y_{t-1}^* \sim \frac{1}{h^*d_2} \sum_{s=1}^T L_1 \left( \frac{X_{s-1} - X_{t-1}^*}{h^*} \right) L_3 \left( \frac{Y_{s-1} - y}{h^*} \right) / \sum_{s=1}^T L_1 \left( \frac{X_{s-1} - X_{t-1}^*}{h^*} \right);$$

2. Based on the bootstrapped sample $\{(X_t^*, Y_t^*)\}_{t=1}^T$, we compute the bootstrapped version of the test statistic: $\hat{\Gamma}_\tau = \frac{Th_{h^*}^{d/2} C_2(\mathbf{Y} \rightarrow \mathbf{X})}{\sigma_{\delta^2}}$;

3. Repeat the steps (1)-(2) $B$ times so that we get $\hat{\Gamma}_{j,\tau}^*$ for $j = 1, \ldots, B$;

4. Compute the bootstrapped $p$-value using $p^* = B^{-1} \sum_{j=1}^B 1(\hat{\Gamma}_{j,\tau}^* > \hat{\Gamma}_\tau)$, where $\hat{\Gamma}_\tau = \frac{Th_{h^*}^{d/2} C_2(\mathbf{Y} \rightarrow \mathbf{X})}{\sigma_{\delta^2}}$ is the test statistic based on the original sample $\{(X_t, Y_t)\}_{t=1}^T$, and for a given significance level $\alpha$, we reject the null hypothesis if $p^* < \alpha$.

In the above bootstrap-based procedure, we have taken the same bandwidth $h^*$ for the nonparametric kernel estimators of the marginal density of $X_{t-1}$ and the conditional densities of $X_t$ and $Y_{t-1}$ given $X_{t-1}$. However, in principle, one can use different bandwidths without invalidating the local smoothed bootstrap. The next theorem establishes the asymptotic validity of the smoothed local bootstrap-based procedure [refer to the proof of Theorem 3 in Appendix A.2].

**Theorem 3** Suppose the assumptions in Theorem 2 and Assumption A.10 hold. Then, we have

$$\hat{\Gamma}_\tau^* := \frac{Th_{h^*}^{d/2} C_2(\mathbf{Y} \rightarrow \mathbf{X})}{\sigma_{\delta^2}} \xrightarrow{d} \mathcal{N}(0, 1)$$

in probability, conditionally on $\{(X_t, Y_t)\}_{t=1}^T$, as $T \to \infty$, where $\hat{\sigma}_{\delta^2}^2$ is analogously defined as in Theorem 2.
The result in theorem 3 provides an asymptotically valid approximation to the limiting null distribution of $\tilde{\Gamma}_\tau$. Regardless of whether the null hypothesis is true or not, this result is valid.

8 Extension: Additional control variables

In this section, we consider an additional control variable $W$, which can play the role of auxiliary variables and transmit a possible indirect causality between the variables of interest $X$ and $Y$. As for the processes $X$ and $Y$, let $\{W_t \in \mathbb{R}, t = 0, \ldots, T\}$ be a sample of strictly stationary stochastic process in $\mathbb{R}$, and denote $W_{t-1} = (W_{t-1}, \ldots, W_{t-d_3})'$, for some fixed known integer $d_3 \geq 1$. Hereafter, we focus on the estimation of the measure of Granger causality in quantiles from $Y$ to $X$ in the presence of $W$. We can, in a similar way, define an estimator of the measure of Granger causality in quantiles from $X$ to $Y$, after controlling $W$.

To simplify the derivation of the main results in the presence of the auxiliary variable $W$, the following unconstrained partially linear quantile regression model is considered, i.e. for a fixed quantile $\tau \in (0, 1)$,

$$X_t = \beta_t' W_{t-1} + m_{1\tau} (Z_{t-1}) + \varepsilon_{1t},$$

(23)

where $Z_{t-1} = (X_{t-1}', Y_{t-1}')'$ is a $d \equiv d_1 + d_2$ dimensional vector that contains the past of $X$ and $Y$, $\beta_t$ is a $d_3$-dimensional vector of unknown parameters, and $\varepsilon_{1t}$ is an error term with its $\tau$-th conditional quantile, conditional on $(W_{t-1}', Z_{t-1}')'$, equal to zero. The quantile regression in (23) is a linear function of the past of $W$ (i.e. $\beta_t' W_{t-1}$) and a nonlinear function of the past of $X$ and $Y$ (i.e. $m_{1\tau} (Z_{t-1})$). It is assumed throughout that the remainder of this section that $\beta_t$ and $m_{1\tau}$ are identified uniquely. For sufficient conditions that guarantee the identification of the model (23), the readers can refer to Theorem 1 of Lee (2003). Partially linear quantile regression models are particularly useful because they compromise flexibly between fully parametric and fully nonparametric models to avoid the loss of precision due to the curse of dimensionality while making weaker assumptions about the functional form of the regression model.

Similarly, the constrained partially linear quantile regression model is given by

$$X_t = \overline{\beta}_t' \overline{W}_{t-1} + \overline{m}_{1\tau} (\overline{X}_{t-1}) + \overline{\varepsilon}_{1t},$$

(24)

where $\overline{X}_{t-1} = (X_{t-1}, \ldots, X_{t-d_1})'$ is a $d_1$-dimensional vector that contains the past of $X$, $\overline{\beta}_t$ is a $d_3$-dimensional vector of unknown parameters, and $\overline{\varepsilon}_{1t}$ is an error term with its $\tau$-th conditional quantile, conditional on $(W_{t-1}', X_{t-1}')'$, equal to zero. Note that the linear parts in the constrained and unconstrained partially linear quantile regressions are similar; thus, the only difference between the two quantile regressions is in the nonlinear parts that depend on different information sets.

Based on the constrained and unconstrained partially linear quantile regressions in (23) and (24), we define the following measure of Granger causality from $Y$ to $X$ through its $\tau$-th quantile, for $\tau \in (0, 1)$, after
controlling for the presence of the auxiliary variable $W$ that might be the source of indirect causality:

$$C_{\tau}^{PL} (Y \rightarrow X|W) = \ln \left( \frac{E \left[ \rho_{\tau} \left( X_t - \beta_\tau W_{t-1} - m_{1\tau} (X_{t-1}) \right) w (Z_{t-1}) \right]}{E \left[ \rho_{\tau} \left( X_t - \beta_\tau W_{t-1} - m_{1\tau} (Z_{t-1}) \right) w (Z_{t-1}) \right]} \right),$$

(25)

where $w(\cdot)$ is a user-chosen weighting function.

We here follow Lee’s (2003) and Sun’s (2005) approaches for the estimation of $\beta_\tau, m_{1\tau}, \beta_\tau$, and $m_{1\tau}$. For more details on the estimation of partially linear quantile regression, the reader can refer to Lee (2003) and Sun (2005). Using estimates of $\beta_\tau, m_{1\tau}, \beta_\tau$, and $m_{1\tau}$, the measure of causality in quantile given control variables $W$ defined in Equation (25) can be consistently estimated using the following estimator:

$$C_{\tau}^{PL} (Y \rightarrow X|W) = \ln \left( \frac{\sum_{t=1}^{T} \rho_{\tau} \left( X_t - \beta_\tau W_{t-1} - m_{1\tau} (X_{t-1}) \right) w (Z_{t-1})}{\sum_{t=1}^{T} \rho_{\tau} \left( X_t - \beta_\tau W_{t-1} - m_{1\tau} (Z_{t-1}) \right) w (Z_{t-1})} \right).$$

(26)

The following two theorems, respectively, provide the Bahadur representation and a non-degenerate asymptotic normal distribution for the nonparametric estimator $C_{\tau}^{PL} (Y \rightarrow X|W)$ in (26), under the null hypothesis $H_0 : C_{\tau}^{PL} (Y \rightarrow X|W) = 0$. The proofs are similar to those of Theorems 1 and 2; hence, only sketched proofs of Theorems 4 and 5 below will be found in Appendix A.2.

**Theorem 4** Let $d = d_1 + d_2$. Suppose Assumptions A.1-A.10 in Appendix A.1 hold, $p > d_1/2 - 1$, $h_1 = O(T^{-\kappa_1})$ with $1/(2p + 2 + d_1) < \kappa_1 < 1/(2d_1)$, $q > d/2 - 1$, and $h_2 = O(T^{-\kappa_2})$ with $1/(2p + 2 + d) < \kappa_2 < 1/(2d)$. Then, for a given $\tau \in (0,1)$, we have

$$\sqrt{T} \left( C_{\tau}^{PL} (Y \rightarrow X|W) - C_{\tau}^{PL} (Y \rightarrow X|W) \right) = (1 + C_{\tau}^{PL} (Y \rightarrow X|W)) \frac{1}{\sqrt{T}} \sum_{t=1}^{T} (e_{t}^{PL} - u_{t}^{PL}) + o_p(1),$$

where

$$e_{t}^{PL} = \frac{\rho_{\tau} \left( X_t - \beta_\tau W_{t-1} - m_{1\tau} (X_{t-1}) \right) w (Z_{t-1}) - E \left[ \rho_{\tau} \left( X_t - \beta_\tau W_{t-1} - m_{1\tau} (X_{t-1}) \right) w (Z_{t-1}) \right]}{E \left[ \rho_{\tau} \left( X_t - \beta_\tau W_{t-1} - m_{1\tau} (X_{t-1}) \right) w (Z_{t-1}) \right]},$$

and

$$u_{t}^{PL} = E \left[ \rho_{\tau} \left( X_t - \beta_\tau W_{t-1} - m_{1\tau} (Z_{t-1}) \right) w (Z_{t-1}) \right] - E \left[ \rho_{\tau} \left( X_t - \beta_\tau W_{t-1} - m_{1\tau} (Z_{t-1}) \right) w (Z_{t-1}) \right].$$

**Theorem 5** Let $d = d_1 + d_2$. Suppose Assumptions A.1-A.10 in Appendix A.1 hold, $p > d_1/2 - 1$, $h_1 = O(T^{-\kappa_1})$ with $1/(2p + 2 + d_1) < \kappa_1 < 1/(2d_1)$, $q > d/2 - 1$, and $h_2 = O(T^{-\kappa_2})$ with $1/(2p + 2 + d) < \kappa_2 < 1/(2d)$. Then, under the null hypothesis $H_0 : C_{\tau}^{PL} (Y \rightarrow X|W) = 0$, for a given $\tau \in (0,1)$, we have

$$Th_2^{d/2} C_{\tau}^{PL} (Y \rightarrow X|W) \xrightarrow{d} \mathcal{N}(0, \sigma_{0\tau}^{PL})^2,$$

where

$$\sigma_{0\tau}^{PL} = \frac{2\tau^2 (1 - \tau)^2}{C_{\tau}^{PL}} \int K^2(u) du \int \frac{w^2(z)}{\mu^2(\hat{s}_1 z^2)} dz.$$

17
with $C_{PL}^\tau = E\left[p_t (X_t - \beta_t' W_{t-1} - m_{1\tau} (Z_{t-1})) \right.$ \left. w \left(Z_{t-1}\right)\right]$, $f_{\varepsilon_t|Z}(0|z)$ is the conditional density of $\varepsilon_t := X_t - \beta_t' W_{t-1} - m_{1\tau} (Z_{t-1})$ given $Z_{t-1} = z$ evaluated at $\varepsilon_t = 0$.

Note that $\sigma_{0PL}^2$ can be estimated consistently by $\tilde{\sigma}_{0PL}^2$ similar as (17). Lastly, as in the aforementioned partially linear quantile regressions, the linear parameter $\beta_t$ [resp. $\tilde{\beta}_t$] can be estimated consistently at the parametric $\sqrt{T}$-rate, which is much faster than the convergence rate of the nonparametric part $m_{1\tau}$ [resp. $\tilde{m}_{1\tau}$], the estimation effect of $\tilde{\beta}_t$ [resp. $\tilde{\tilde{\beta}}_t$] is asymptotically negligible; hence, it is possible to derive the above results for the causality measure from $Y$ to $X$ replacing $X_t$ by $\tilde{X}_t = X_t - \beta_t' W_{t-1}$ [resp. $X_t - \tilde{\beta}_t' W_{t-1}$] as if $\beta_t$ [resp. $\tilde{\beta}_t$] were known.

## 9 Monte Carlo simulations

In this section, we conduct a Monte Carlo simulation study to investigate the performance of the bootstrap-based test, which we proposed previously for testing the statistical significance of our measures of Granger causality in quantiles. Our primary interest is to evaluate the empirical size and power of the test in Theorem 3. Further, we will compare with size and power of Jeong et al.’s (2012) nonparametric test for testing the Granger noncausality in quantile.

All through this section, we consider two univariate time series processes $X_t$ and $Y_t$. The null hypothesis of interest corresponds to Granger non-causality in quantile from $Y$ to $X$; i.e. $H_0 : C_{\tau}(Y \rightarrow X) = 0$, for a given quantile $\tau \in (0, 1)$. In the sequel, $\eta_t$ and $\varepsilon_t$ are two independent sequences of independently and identically distributed (i.i.d.) standard normal random variables.

### 9.1 Bootstrap-based Test

Though the asymptotic-based test $\hat{\Gamma}_\tau$ in (18), given by Theorem 2, is not time consuming and easy to implement, the empirical size of the test statistic $\hat{\Gamma}_\tau$ in small samples may differ significantly from that of the significance level. The size distortion is almost unavoidable for small samples, which has been confirmed in our unreported simulations. However, it is also known that some types of bootstrap such as smoothed local bootstrap or moving block bootstrap can help eliminate or mitigate the asymptotically negligible higher order terms, which may have a substantial and adverse effect on the size of $\hat{\Gamma}_\tau$. Additional benefits of using smoothed local bootstrap-based test are that it can handle the unknown form of dependence in the data and it is not very sensitive to changes in the bandwidth parameter. Thus, our primary interest is to evaluate the empirical size and power of the bootstrap-based test in Theorem 3 using the data generating processes (DGPs) presented in Table 1.

Before we discuss the DGPs in Table 1, we should recall the following. Assume that the variable $X_t$ is a linear/nonlinear function of its own past, $I_X(t-1)$, and the past of $Y$, $I_Y(t-1)$. Formally, consider the
Table 1: Data generating processes

<td>( Y_t = -0.3Y_{t-1} + \varepsilon_t )</td>
<td>( X_t = 0.65X_{t-1} + \sqrt{1 + Y_{t-1}^2} \eta_t )</td>
</tr>
</tbody>
</table>

Note: This table summarizes the DGPs, which we consider in the simulation study, to investigate the properties (size and power) of nonparametric test of causality measures in quantiles. We simulate \((Y_t, X_t), for t = 1, \ldots, T, under the assumption that \((\varepsilon_t, \eta_t)\) are i.i.d from \(N(0, I_2)\) with \(I_2\) the 2 \times 2 identity matrix. The last column of the table summarizes the directions of causality and non-causality in each DGP. “\( \rightarrow \)” and “\( \not\rightarrow \)” refer to Granger causality and non-causality, respectively.
following mean regression equation:

$$X_t = \mu (I_X(t-1), I_Y(t-1)) + \varepsilon_t,$$

(27)

where $\varepsilon_t$ is an error term that satisfies $E [\varepsilon_t | I_X(t-1), I_Y(t-1)] = 0$. The latter assumption implies that $$E (X_t | I_X(t-1), I_Y(t-1)) = \mu (I_X(t-1), I_Y(t-1)).$$

Now, if we further assume that $\varepsilon_t$ is a $N(0, \sigma^2)$, then the $\tau$-th quantile of $X_t$, conditional on the past $I_X(t-1) \cup I_Y(t-1)$, will be given by

$$Q^\tau (X_t | I_X(t-1), I_Y(t-1)) = \mu (I_X(t-1), I_Y(t-1)) + \Phi^{-1} (\tau) \sigma, \text{ for } \tau \in (0, 1),$$

(28)

where $\Phi(\cdot)$ is the cumulative distribution function of the standard normal $N(0, 1)$.

Equations (27) and (28) show that under normality assumption of the error term $\varepsilon_t$, linear/nonlinear Granger (non-)causality in mean from $Y$ to $X$ is equivalent to linear/nonlinear Granger (non-)causality in quantiles from $Y$ to $X$. Consequently, since the error terms in Table 1 are assumed to be normally distributed, (non-)causality in terms of the mean implies (non-)causality in quantiles. Thus, the seven DGPs in Table 1 will be used to evaluate the empirical size and power of the bootstrap-based test in Theorem 3. The last column of this table summarizes the directions of (non-)causality in quantiles in those DGPs. Since in this DGP the null hypothesis is satisfied, the first DGP (DGP S1) of $Y$ and $X$ is used to investigate the size property. However, in DGP P1 to DGP P6 of $Y$ and $X$, the null hypothesis is not satisfied, and therefore, those GDPs serve the purpose of illustrating the power of our test. Further, notice that DGP P2 to DGP P6 are highly nonlinear and DGP P6 is taken from Example 1 in our motivating section. All DGPs under consideration are strictly stationary and ergodic processes.

For the estimation of nonparametric quantile regressions, consequent to the measures of Granger causality in quantiles, we use the nonparametric estimator defined in (14) with a polynomial order of $p = 1$ (i.e. local linear estimator). The weight function $w(\cdot)$ in the estimator of the measure in Equation (13) is set to be equal to one everywhere, i.e. the trivial weight function, given that the performance here is not depending heavily on the weight function. Further, to estimate the conditional restricted and unrestricted quantile regression functions, we take the univariate kernel function $K(\cdot)$ equal to the standard normal density. For the multivariate case, we use the product kernel.

The bandwidths used to estimate the univariate (restricted) and bivariate (unrestricted) quantile regressions have the forms $h_1 = c_1 \ast n^{-1/5}$ and $h_2 = c_2 \ast n^{-1/6}$, respectively, where $c_1$ and $c_2$ are selected using the cross-validation technique for quantile estimation, refer to Tong and Yao (2000) and Noh, et al. (2013) among others.\footnote{Following Noh, et al. (2013), we select $c_1$ and $c_2$ which minimize the criterion

$$CV(c_j) = \sum_{t=1}^{T} \rho_r (X_t - \hat{m}_{t, r} (\cdot)) w (Z_{t-1}), \text{ for } j = 1, 2.$$}

For simplicity, the bandwidth $h^*$, used to generate the bootstrap samples, is assumed to

Note: This table reports the empirical size and the power of the local bootstrap-based test in Theorem 3 for testing the Granger non-causality in quantiles from \( Y \) to \( X \) at \( \alpha = 5\% \) significance level. The number of simulations is equal to 500 and the number of bootstrap resamples is \( B = 199 \).

take the same values as the above univariate bandwidth \( h_1 \). How to choose the bandwidths \( h_1 \) and \( h_2 \) to maximize our test’s power is not yet investigated and requires more attention in future studies. Gao and Gijbels (2008) have proposed to use the Edgeworth expansion of the asymptotic distribution of the test in order to choose the bandwidth such that the power function of the test is maximized while the size function is controlled.

Three sample sizes \( T = 50, 100 \) and \( 200 \) are considered. For each DGP, we first generate \( T + 300 \) observations and then discard the first 300 observations to minimize the potential adverse effect of the initial values. We use 500 simulations to compute the empirical size and power. For each Simulation, we use \( B = 199 \) bootstrap replications. Finally, we focus on the nominal size 5\% and we report the results for three different quantiles: \( \tau = 0.25, 0.50, \) and 0.75.

with \( \hat{m}_{-t,1\tau}() = \hat{m}_{-t,1\tau} (X_{t-1}) \) and \( \hat{m}_{-t,2\tau}() = \hat{m}_{-t,1\tau} (Z_{t-1}) \).
Table 2 reports the empirical size and power of the bootstrapped test statistic $\hat{\Gamma}_T^*$ in Theorem 3. As expected, the local bootstrap-based test controls its size for both small and moderate samples. Concerning the power, Table 2 shows that this test has a reasonable power against various alternatives. Its power is low for $T = 50$; however, it rapidly increases as we increase the sample size to $T = 100$ and 200. Hence, given the small and moderate samples that are under consideration, the performance of local bootstrap-based test is satisfactory for the quantiles examined.

9.2 Comparison with Jeong et al.’s (2012) test

We saw in Section 6.2 that testing that the causality measure is equal to zero is equivalent to testing for Granger non-causality in quantile. Thus, the tests in Theorems 2 and 3 can be viewed as tests of Granger non-causality in quantile. Jeong et al. (2012) have recently proposed a nonparametric test for nonlinear Granger causality in quantiles. For $\beta$-mixing processes and under the null hypothesis of non-causality in quantile, the asymptotic distribution of Jeong et al.’s (2012) test statistic is given by a standard normal distribution. However, Jeong et al. (2012) do not provide a bootstrap-based test as we have done in this study.

In this subsection, we consider an additional simulation exercise to compare the empirical size and power of our bootstrap-based test in Theorem 3 with those of Jeong et al.’s (2012) nonparametric test. We generate data according to the following model adapted from DGP P6 in Table 1:

\[
\begin{align*}
X_t &= 0.65X_{t-1} + \sqrt{1 + cY_{t-1}^2}\eta_t, \\
Y_t &= -0.3Y_{t-1} + \varepsilon_t,
\end{align*}
\]

where $c$ is a non-negative constant and $\varepsilon_t$ and $\eta_t$ are independent standard normal random variables. Here, $c = 0$ corresponds to the null hypothesis of non-causality from $Y$ to $X$. Thus, the above DGP under $c = 0$ is used to investigate the size property of the two tests. However, the null hypothesis is not satisfied when $c > 0$, and therefore the above GDP under $c > 0$ serves to illustrate the power of the tests. It is worthwhile to notice that, when $c > 0$, there is no causality in the mean from $Y$ to $X$, but there is causality in quantiles from $Y$ to $X$. To investigate the power of both tests, we take $c = 0.3, 0.5, 0.7, 0.9, 1.1$, such that the higher $c$ is the stronger the causality from $Y$ to $X$ is. The empirical size and power of our bootstrap-based test are computed using 500 replications and 199 bootstraps; results for Jeong et al.’s (2012) test are based on 1000 replications and critical values from standard normal distribution. Furthermore, for the purpose of making fair comparison, for our test, we use the following univariate bandwidth $h_1 = n^{-1/5}$ and bivariate bandwidths $h^1 = h^2 = h_2 = n^{-1/6}$, and for Jeong et al.’s (2012) test, the same univariate bandwidth $h_1 = n^{-1/5}$ is adopted. To facilitate the comparison of the finite-sample performances of the two tests, sample sizes $T = 50, 100, \text{ and } 200$ are considered. Finally, the nominal size 5% is considered.

</table>

Note: This table reports and compares the empirical size and power of our local bootstrap-based test [hereafter ST] and the asymptotic test of Jeong et al.’s (2012) [hereafter JHS] for testing Granger non-causality in quantile from $Y$ to $X$ at $\alpha = 5\%$ significance level. The number of simulations is equal to 500 and the number of bootstrap resamples is $B = 199$. 

Table 3 compares the empirical size and power of our bootstrap-based test with those of Jeong et al.’s (2012) test for testing the non-causality in quantile from $Y$ to $X$ at $\alpha = 5\%$ significance level. From this, we observe that under the null hypothesis [column $c = 0$], there is a serious size distortion (oversized) for the Jeong et al.’s (2012) test, while, as expected, our bootstrap-based test is able to preserve the size well. This result is consistent across different levels of quantiles and sample sizes under examination. In addition, the power of Jeong et al.’s (2012) test is almost always dominated by the power of bootstrapped-based test, especially for slightly larger $c$’s and $T = 100, 200$, even after ignoring the oversized problem of their asymptotic-based test. This illustrates the usefulness of using a bootstrap-based test for finite sample studies.

10 Empirical application

This section aims to apply the causality measures, proposed in the previous sections to quantify and compare the predictability of quantiles of conditional distribution of stock returns using several economic and financial variables. The ultimate objective is to find which of these variables—financial or macro variables—help predict better the quantiles of stock returns.

The issue of predicting the conditional distribution of stock returns using quantile regressions has been the focus of many recent studies. For example, Chuang, Kuan, and Lin (2009) have investigated the causality (predictability) between stock return and volume based on parametric quantile regressions. Using a sup-Wald-type test for testing the Granger non-causality in all quantiles, they found that the causality from volume to return is usually heterogeneous across quantiles. In particular, the quantile causal effects of volume on return exhibit a spectrum of (symmetric) V-shape relations so that the dispersion of return distribution increases with lagged volume. Cenesizoglu and Timmermann (2007) have also used a parametric quantile regression framework to look at whether a range of common predictor variables proposed in the finance and macro literature (e.g. Book to Market Ratio, Dividend Yield, Dividend Price Ratio, Inflation, T-bill, Stock Variance, Earnings Price Ratio, etc.) are helpful in predicting (Granger causing) specific quantiles of the stock return distribution. Empirically, they found little evidence to suggest that the center of the return distribution can be predicted. However, their main findings suggest that the tails of stock returns can be predicted by means of state variables proposed in the literature. Yang, Tu, and Zeng (2014) have applied parametric regression models to investigate the Granger causality in terms of the mean and quantiles between stock returns and exchange rate for nine Asian markets. Their empirical results show that there are more bi-directional causal relations based on the quantile regression than the conventional mean regression. Finally, Engle and Manganelli (2004) have used nonlinear parametric regressions to model the Value-at-Risk (VaR) of stock returns, which corresponds to predicting lower quantiles of the distribution of returns.
Thus, most existing works, focus on the predictability of quantiles of stock return distribution based on the parametric quantile regressions. In this section, we consider nonparametric predictability of quantiles of stock returns using several economic and financial variables. The nonparametric causality measures, proposed in the previous sections, do not impose any restriction on the model linking the dependent variable (stock return) to the independent variable (financial/macroeconomic variables).

Our data consist of monthly aggregate S&P 500 index over the period of January 1990 to December 2014 and monthly Variance Risk Premium, Unemployment rate, Inflation, Effective Federal Funds rate, over the period January 1990 to December 2014. Theoretically, the variance risk premium is defined as the difference between the ex-ante risk neutral expectation of the future stock return variance and the expectation of stock return variance between time \( t \) and \( t + 1 \):

\[
VRP_t \equiv E^Q_t (\text{Var}_{t,t+1}) - E^P_t (\text{Var}_{t,t+1}) ,
\]

where \( \text{Var}_{t,t+1} \) is the variance of stock return between time \( t \) and \( t + 1 \), \( E^Q_t \) denotes the conditional expectation with respect to risk-neutral probability, and \( E^P_t \) denotes the conditional expectation with respect to the physical probability. \( VRP_t \) in Equation (29) is unobservable, since the quantities \( E^Q_t (\text{Var}_{t,t+1}) \) and \( E^P_t (\text{Var}_{t,t+1}) \) are unobservable. Estimating \( VRP_t \) depends on the estimation of risk neutral and physical expectations:

\[
\hat{VRP}_t \equiv \hat{E}^Q_t (\text{Var}_{t,t+1}) - \hat{E}^P_t (\text{Var}_{t,t+1}) .
\]

In practice, \( \hat{E}^Q_t (\text{Var}_{t,t+1}) \) and \( \hat{E}^P_t (\text{Var}_{t,t+1}) \) are commonly replaced by the squared-Volatility Index (VIX) and the realized variance \( RV_{t,t+1} \), respectively. VIX is provided by the Chicago Board Options Exchange (CBOE), and is calculated using the near term S&P 500 options markets. It is based on the highly liquid S&P500 index options along with the "model-free" approach. In the literature there is no unique approach to constructing the physical expectation \( \hat{E}^P_t (\cdot) \). Bollerslev et al. (2009) and Zhou (2010) have estimated reduced-form multi-frequency autoregression with potentially multiple lags for \( \hat{E}^P_t (\text{Var}_{t,t+1}) \). Following Bollerslev et al. (2009) and Zhou (2010), we use time-\( t \) realized variance \( RV_{t,t-1} \), which ensures that the variance risk premium proxy for predicting various risk premia is in the time \( t \) information set and would be a correct choice if the realized variance process were unit-root.

Finally, our analysis is based on the logarithmic return of the S&P 500 index. Further, the macro variables were transformed using the first-difference in log.

10.1 Empirical results

Table 4 presents the results of estimating the measures of Granger causality in quantiles from variance risk premium, unemployment rate, inflation, and effective federal funds rate to S&P 500 stock returns. Further,

</table>

Note: This table reports the results of the estimation and inference for measures of Granger causality (predictability) in quantiles from variance risk premium (VRP), Unemployment rate (UNEMP), Inflation (INFL), Effective Federal Funds rate (EFF) to S&P 500 risk premium (RP). **"** means the statistical significance at 5% significance level. The sample size is calculated from January 1990 to December 2014.

The table reports the p-values for testing the statistical significance of the estimates of the measures using the bootstrap-based test introduced in Section 7.

Table 4 shows that the degree of predictability (causality) of quantiles of stock returns using variance risk premium is much higher compared to that of the other three variables. The degree is even higher at the median compared to the 0.25-th and 0.75-th quantiles of stock returns. Thus, the variance risk premium affects more the center of the distribution of stock returns. The estimates of the measures at different quantiles of stock returns are statistically significant at 5% significance level.

Thereafter, the degree of predictability of quantiles of stock returns, using effective federal funds rate, is also high compared to those produced by unemployment rate and inflation. The estimates of the measures are statistically significant at 5% significance level for the 0.25-th and 0.75-th quantiles; however, not so
for the median, which indicates that the effective federal funds rate only affects the left and right tails of the distribution of stock returns, but not its center. Finally, it seems that the degrees of predictability of quantiles of stock returns using unemployment rate and inflation are weak and statistically insignificant.

Finally, the above results show that only financial variables help predict quantiles of S&P 500 stock returns. On the contrary, the economic and statistical significances of the causal effect of macro variables on quantiles of stock returns are not significant.

11 Conclusion

We have introduced new measures of Granger causality in quantiles that are able to detect and quantify nonlinear causal effects between random variables. The measures are based on nonparametric quantile regressions and defined as logarithmic function of restricted and unrestricted expectations of quantile check loss functions. They can be easily and consistently estimated by replacing the unknown expectations of check loss functions by their nonparametric kernel estimates. We derived a Bahadur-type representation for the nonparametric estimator of the measures. We provided the asymptotic distribution of this estimator, which can be used to build tests for the statistical significance of the measures. We also examined the properties of the latter tests under certain local alternatives. Thereafter, we established the validity of a smoothed local bootstrap, which one can use in finite-sample settings, to perform statistical tests. A Monte Carlo simulation study revealed that the bootstrap-based test has a good finite-sample size and power properties for a variety of data-generating processes and different sample sizes.

Using the above nonparametric test for testing the null hypothesis that the true value of measure is equal to zero is equivalent to testing for noncausality in quantile. Thus, our test can be viewed as a competitor of the exiting nonparametric tests of Granger causality in quantile. There is only one nonparametric test of Granger causality in quantile, which is proposed by Jeong et al. (2012). We considered an additional simulation exercise to compare the empirical size and power of our test with those of Jeong et al.’s (2012) test. The simulation results indicate that our test controls the size and has a better power than Jeong et al.’s (2012) test.

Finally, the empirical importance of measuring Granger causality in quantiles was illustrated. We quantified the degree of nonlinear predictability of quantiles of equity risk premium using the variance risk premium, unemployment rate, inflation, and the effective federal funds rate. The empirical results showed that the variance risk premium and effective federal funds rate have strong predictive power for predicting the quantiles of risk premium, compared to that of the predictive power of the other two macro variables. In particular, the variance risk premium is able to predict the center, the lower and upper quantiles of the distribution of risk premium, whereas the effective federal funds rate only predicts the lower and upper
quantiles. However, the unemployment rate and inflation have no effect on the quantiles of risk premium.

Appendix A

A.1 Assumptions

In this appendix, we provide the necessary assumptions needed to derive the theoretical results in the paper. We consider a set of standard assumptions that have been widely used in the literature on nonparametric estimation and inference; see for example Kong et al. (2010) and Noh et al. (2013) among others.

First of all, let \(\{(X_t, Y_t)\}\) be a jointly stationary process. Since we are interested in time series data, we need to specify the dependence in the processes of interest. In what follows, we define the mixing dependence

that we consider in this paper. The stationary stochastic process \( \{(X_t, Y_t)\} \) is strongly mixing, with \( \gamma(k) \) its strong mixing coefficient, if

\[
\gamma(k) = \sup_{A \in \mathcal{F}_0^\infty, B \in \mathcal{F}_k^\infty} |\mathbb{P}(AB) - \mathbb{P}(A) \mathbb{P}(B)| \to 0 \quad \text{as} \quad k \to \infty,
\]

with \( \mathcal{F}_a^b = \sigma \left( \{(X_t, Y_t)\}_{t=a}^b \right) \), where \( \sigma(\cdot) \) means the smallest sigma algebra. Furthermore, let \( V_x \) and \( V_z \) be two open convex sets in \( \mathbb{R}^{d_1} \) and \( \mathbb{R}^{d_1+d_2} \), respectively. We now consider the following assumptions:

**A.1.** The processes \( \{(X_t, Y_t)\} \) are strongly mixing with mixing coefficients \( \gamma(k) \) satisfying

\[
\sum_{k=1}^{\infty} k^{\alpha} [\gamma(k)]^{1-2/\nu_2} < \infty,
\]

for some \( \nu_2 > 2 \) and \( \alpha > \max\{(p+d_1+1)(1-2/\nu_2)/d_1, (q+d_1+d_2+1)(1-2/\nu_2)/(d_1+d_2)\} \).

**A.2.** All partial derivatives of \( m_{1T}(z) \) up to order \( p+1 \) exist and are continuous for all \( z \in V_z \), and there exists a constant \( C_1 > 0 \) such that \( |D^j m_{1T}(z)| \leq C_1 \), for all \( z \in V_z \) and \( |r| = p+1 \). All partial derivatives of \( m_{1T}(z) \) up to order \( q+1 \) exist and are continuous for all \( z \in V_z \), and there exists a constant \( C_2 > 0 \) such that \( |D^j m_{1T}(z)| \leq C_2 \), for all \( z \in V_z \) and \( |r| = q+1 \).

**A.3.** The marginal density of \( \varepsilon_{1t} = X_t - m_{1T}(Z_{t-1}) \) is bounded and satisfies \( E(\varphi(\varepsilon_{1t})|Z_{t-1}) = 0 \).

**A.4.** For all \( e \) in a neighbourhood of zero, the conditional density \( f_{\varepsilon_{1}\mid Z_{-1}}(e|z) \) of \( \varepsilon_{1t} = X_t - m_{1T}(Z_{t-1}) \) given \( Z_{t-1} = z \) satisfies

\[
\left| f_{\varepsilon_{1}\mid Z_{-1}}(e|z_1) - f_{\varepsilon_{1}\mid Z_{-1}}(e|z_2) \right| \leq K_e \|z_1 - z_2\|,
\]

where \( K_e \) is a positive constant depending on \( e \). Further, the conditional density is positive for \( e = 0 \) for all values of \( z \in V_z \), and its first partial derivative with respect to \( e \), \( D^1 f_{\varepsilon_{1}\mid Z_{-1}}(e|z) \), is bounded for all \( z \in V_z \) and \( e \) in a neighbourhood of zero.

**A.5.** The weight function \( w(z) \) is continuous, and its support \( \mathcal{D} \subset V_z \) is compact and has non-empty interior.

**A.6.** The kernel function \( K(\cdot) \) has a compact support and \( \left| H_j^z(u) - H_j^z(v) \right| \leq \|u - v\| \) for all \( j \) with \( 0 \leq j \leq \max\{2p+1, 2q+1\} \), where \( H_j^z(u) = \hat{w}^j K(u) \).

**A.7.** The probability density function of \( Z_{t-1} \), \( f_{Z_{t-1}}(z) \), is positive and bounded with bounded first-order derivatives on \( V_z \). The joint probability density of \( (Z_0, Z_t) \) satisfies \( f_{(Z_0, Z_t)}(u, z; l) \leq C < \infty \) for all \( l \geq 1 \).

**A.8.** The conditional density \( f_{Z_{t-1}|X} \) of \( Z_{t-1} \) given \( X_t \) exists and is bounded. The conditional density function \( f_{(Z_0, Z_t)|(X_1, X_{t+1})} \) of \( (Z_0, Z_t) \) given \( (X_1, X_{t+1}) \) exists and is bounded for all \( l \geq 1 \).
A.9. The bandwidth sequences \( h_1 \) and \( h_2 \) satisfy \( h_1 \to 0, Th_1^{d_1+2(p+1)}/\log T = O(1), h_2 \to 0, \) and \( Th_2^{d_1+d_2+2(q+1)}/\log T = O(1) \) as \( T \to \infty \). Furthermore, we assume \( Th_2^{2(d_1+d_2)}/(\log T)^3 \to \infty, h_1 = o(h_2), \) and \( h_2^{d_1+d_2} = o(h_1^{d_1}) \).

A.10. The bootstrap bandwidth \( h^* \) satisfies \( h^* \to 0 \) and \( Th^*^{d_1+d_2+2(q+1)}/(\log T)\lambda = O(1) \), for some \( \lambda > 0 \) as \( T \to \infty \).

The assumptions presented here are frequently seen for nonparametric smoothing in multivariate time series analysis, see Masry (1996) and Kong et al. (2010). Assumptions A.1-A.2, A.6-A.8 and A.9 are standard. Assumptions A.4 and A.5 are required to derive the Bahadur representations in Lemmas 3-4 in Appendix B. Assumption A.10 is assumed to guarantee the consistency of the smoothed local bootstrap.

A.2 Proofs of the main results

This appendix provides the proofs of the main theoretical results developed in Sections 6, 7, and 8.

**Proof of Theorem 1:** Theorem 1 can be proved by combing the first order Taylor expansion of \( C_r(Y \to X) \) around 1 (i.e. using \( \ln y \approx y - 1 \)) and the asymptotic Bahadur representations in Lemmas 3 and 4 of Appendix B and with the equality \( \hat{\alpha}/\hat{b} = a/b + \hat{b}^{-1}[(\hat{\alpha} - a) - (\hat{b} - b)(a/b)] \). \( \square \)

**Proof of Theorem 2:** Note that for any \( x, y \),

\[
\rho_r(x - y) - \rho_r(x) = (-y)\varphi(x) + 2(y - x)[1(y > x > 0) - 1(y < x < 0)].
\]

Let \( \hat{d}(x) = \hat{m}_{1r}(x) - \bar{m}_{1r}(x) \) and \( \tilde{d}(z) = \hat{m}_{1r}(z) - m_{1r}(z) \). By straightforward calculation, under the null hypothesis of no causality, we obtain

\[
\frac{1}{T} \sum_{t=1}^{T} \rho_r(X_t - \hat{m}_{1r}(X_{t-1}))w(Z_{t-1}) - \frac{1}{T} \sum_{t=1}^{T} \rho_r(X_t - \bar{m}_{1r}(Z_{t-1}))w(Z_{t-1}) = \frac{1}{T} \sum_{t=1}^{T} \left[ (\hat{m}_{1r}(Z_{t-1}) - m_{1r}(Z_{t-1})) - (\bar{m}_{1r}(Z_{t-1}) - \bar{m}_{1r}(X_{t-1})) \right] w(Z_{t-1}) \varphi(\varepsilon_{1t})
\]

\[
+ \frac{2}{T} \sum_{t=1}^{T} (X_t - \hat{m}_{1r}(Z_{t-1})) \left\{ 1(\hat{d}(Z_{t-1}) > \varepsilon_{1t} > 0) - 1(\hat{d}(Z_{t-1}) < \varepsilon_{1t} < 0) \right\} w(Z_{t-1})
\]

\[
- \frac{2}{T} \sum_{t=1}^{T} (X_t - \bar{m}_{1r}(X_{t-1})) \left\{ 1(\tilde{d}(X_{t-1}) > \varepsilon_{1t} > 0) - 1(\tilde{d}(X_{t-1}) < \varepsilon_{1t} < 0) \right\} w(Z_{t-1})
\]

\[
:= A_T + B_T + C_T.
\]

From the above decomposition, we will show that under the assumed assumptions, the term \( A_T \) is asymptotically normal, and the terms \( B_T \) and \( C_T \) are asymptotically negligible.

Now, let us first show the asymptotic negligibility of term \( B_T \). Define \( I(w) = \{ t : Z_{t-1} \in D, t = 1, \ldots, T \} \).
Note that $X_t - \hat{m}_{1r}(Z_{t-1}) = -\hat{a}(Z_{t-1}) + \varepsilon_{1t}$. Then,

$$|B_T| \leq \frac{2}{T} \sum_{t=1}^{T} w(Z_{t-1}) |X_t - \hat{m}_{1r}(Z_{t-1})| 1(|\varepsilon_{1t}| < |\hat{a}(Z_{t-1})|)$$

$$\leq \frac{2}{T} \sum_{t=1}^{T} w(Z_{t-1}) \left(|\hat{a}(Z_{t-1})| + |\varepsilon_{1t}|ight) 1(|\varepsilon_{1t}| < |\hat{a}(Z_{t-1})|)$$

$$\leq \frac{4}{T} \sum_{t=1}^{T} w(Z_{t-1}) |\hat{a}(Z_{t-1})| 1(|\varepsilon_{1t}| < |\hat{a}(Z_{t-1})|)$$

$$\leq 4 \max_{t\in I(w)} |\hat{a}(Z_{t-1})| \max_{z\in \mathcal{D}} w(z) \frac{1}{T} \sum_{t=1}^{T} \left(|\varepsilon_{1t}| < \max_{s\in I(w)} |\hat{a}(Z_{s-1})|\right).$$

From the Glivenko-Cantelli Theorem for strictly stationary sequences, we have

$$\sup_{a\in \mathbb{R}} \left|\frac{1}{T} \sum_{t=1}^{T} 1(|\varepsilon_{1t}| < a) - Pr(|\varepsilon_1| < a)\right| = O_p\left(T^{-1/2}\right),$$

It thus follows that

$$|B_T| \leq 4 \max_{t\in I(w)} |\hat{a}(Z_{t-1})| \max_{z\in \mathcal{D}} w(z) \left\{Pr\left(|\varepsilon_1| < \max_{t\in I(w)} |\hat{a}(Z_{t-1})|\right) + O_p\left(T^{-1/2}\right)\right\}$$

$$= 4 \max_{t\in I(w)} |\hat{a}(Z_{t-1})| \max_{z\in \mathcal{D}} w(z) \left\{F_{\varepsilon_{1}} \left(\max_{t\in I(w)} |\hat{a}(Z_{t-1})|\right) - F_{\varepsilon_{1}} \left(- \max_{t\in I(w)} |\hat{a}(Z_{t-1})|\right)\right\}$$

$$+ 4 \max_{t\in I(w)} |\hat{a}(Z_{t-1})| \max_{z\in \mathcal{D}} w(z) O_p\left(T^{-1/2}\right)$$

$$\leq C \left(\max_{t\in I(w)} |\hat{a}(Z_{t-1})|\right)^2 + CT^{-1/2} \max_{t\in I(w)} |\hat{a}(Z_{t-1})|,$$

where the third step follows from the Taylor expansion of $F_{\varepsilon_{1}}$, bounded marginal density of $\varepsilon_{1t}$ in Assumption A.3, and bounded weight function $w(\cdot)$ in Assumption A.5. From Kong et al. (2010), we have

$$\max_{t\in I(w)} |\hat{a}(Z_{t-1})| = O_p\left(\frac{\log T}{Th_2^d}\right)^{3/4},$$

It follows that $B_T = O_p\left(\left(\frac{\log T}{Th_2^d}\right)^{3/4} + T^{-1/2} \left(\frac{\log T}{Th_2^d}\right)^{3/4}\right) = o_p\left(\left(Th_2^{d/2}\right)^{-1}\right)$ under Assumption A.9.

Similar to the term $B_T$, it can be proved that the term $C_T = o_p\left(\left(Th_2^{d/2}\right)^{-1}\right)$ under $h_2^d = o(h_1^{d_1})$ in Assumption A.9. It follows that it is sufficient to establish that $Th_2^{d/2} A_T$ converges in distribution to a normal random variable with asymptotic variance given by $\tilde{\sigma}_{0r}^2 := C_r^2 \sigma_{0r}^2$, for $C_r = E\left[\rho_r \left(X_t - m_{1r}(Z_{t-1})\right) w(Z_{t-1})\right].$
Using Lemmas 1 and 2 of Appendix B, we have

\[
A_T = - \frac{1}{T(T-1)} \sum_{t=1}^{T} \sum_{s=1, s \neq t}^{T} w(Z_{t-1}) E_{t-1} \left[ \frac{H_T^{-1}}{h_T^2} S_{T,q}^{-1}(Z_{t-1}) K_{h_T}(Z_{s-1} - Z_{t-1}) \mu(Z_{s-1} - Z_{t-1}) \varphi(\varepsilon_{1t}) \varphi(\varepsilon_{1s}) \right]
\]

\[
+ \frac{1}{T(T-1)} \sum_{t=1}^{T} \sum_{s=1, s \neq t}^{T} w(Z_{t-1}) E_{t-1} \left[ \frac{H_T^{-1}}{h_T^2} S_{T,p}^{-1}(X_{t-1}) K_{h_T}(X_{s-1} - X_{t-1}) \mu(X_{s-1} - X_{t-1}) \varphi(\varepsilon_{1t}) \varphi(\varepsilon_{1s}) \right]
\]

\[+ o_p \left( (Th_2^{d/2})^{-1} \right)\]

\[:= A_{1T} + A_{2T} + o_p \left( (Th_2^{d/2})^{-1} \right), \]

where the negligible terms with \(t = s\) have been dropped to apply \(U\)-statistic theory due to the leave one observation out in the estimation part. We will show that \(Th_2^{d/2}A_{1T}\) converges in distribution and \(A_{2T} = o_p \left( (Th_2^{d/2})^{-1} \right)\) under our assumptions. First of all, to facilitate our analysis, from the notion of “equivalent kernel” representation for local polynomial estimator [see Fan and Gijbels, 1996, pp.63-64], we get

\[
A_{1T} = \frac{1}{T(T-1)} \sum_{t=1}^{T} \sum_{s=1, s \neq t}^{T} \frac{w(Z_{t-1})}{f_{\varepsilon_1 \mid (0)Z_{t-1}} f_{\varepsilon_2 \mid (0)Z_{t-1}}} K_{h_T}(Z_{t-1} - Z_{s-1}) \varphi(\varepsilon_{1t}) \varphi(\varepsilon_{1s}) + o_p \left( (Th_2^{d/2})^{-1} \right)
\]

\[\equiv A_{1T} + o_p \left( (Th_2^{d/2})^{-1} \right), \quad \text{say.}\]

Note that we can rewrite \(Th_2^{d/2}A_{1T}\) into a standard \(U\)-statistic form with a symmetrized kernel depending on the sample size \(T\), i.e.

\[
Th_2^{d/2}A_{1T} = \frac{2}{T-1} \sum_{1 \leq t < s \leq T} U_T(\chi_t, \chi_s),
\]

where \(\chi_t = (Z_{t-1}, \varepsilon_{1t})\), \(U_T(\chi_t, \chi_s) = \eta_T(\chi_t, \chi_s) + \eta_T(\chi_s, \chi_t)\), and

\[
\eta_T(\chi_t, \chi_s) = \frac{w(Z_{t-1})}{2 f_{\varepsilon_1 \mid (0)Z_{t-1}} f_{\varepsilon_2 \mid (0)Z_{t-1}}} \frac{1}{h_T^2} K \left( \frac{Z_{t-1} - Z_{s-1}}{h_T} \right) \varphi(\varepsilon_{1t}) \varphi(\varepsilon_{1s}).
\]

Note that \(E[U_T(\chi_t, \chi_s)] = E[\eta_T(\chi_t, \chi_s)] = E[U_T(\chi_t, \chi_s) \mid \chi_t] = E[\eta_T(\chi_t, \chi_s) \mid \chi_t] = 0\) under Assumption A.3. So the previous \(U\)-statistic is a degenerate second order \(U\)-statistic. We can apply a central limit theorem (CLT) for second order degenerate \(U\)-statistic with strong mixing processes. Under Assumptions A.1, A.3, A.6, and A.9, one can verify that the conditions of Theorem A.1 in Gao (2007) are satisfied for kernel \(U_T(\chi_t, \chi_s)\) so that a CLT applies to the term \(Th_2^{d/2}A_{1T}\). Its asymptotic variance is given by

\[
\sigma^2 = \lim_{T \to \infty} 2E_t E_s [U_T^2(\chi_t, \chi_s)] = \lim_{T \to \infty} 2E_t E_s \left[ \eta_T(\chi_t, \chi_s)^2 + \eta_T(\chi_t, \chi_t)^2 + 2\eta_T(\chi_t, \chi_s)\eta_T(\chi_s, \chi_t) \right]
\]

\[= 2\tau^2 (1 - \tau)^2 \int K^2(u) du \int \frac{w^2(z)}{f_{\varepsilon_1 \mid (0)Z_{t-1}} f_{\varepsilon_2 \mid (0)Z_{t-1}}} dz \]

\[:= C_\tau^2 \sigma^2 \]

34
where $E_t$ denotes the expectation with respect to $\chi_t$. For example, by straightforward calculation of conditional expectation, we have
\[
\lim_{T \to \infty} E_t E_s \left[ \eta_T(\chi_t, \chi_s)^2 \right] = \frac{1}{4} \tau^2 (1 - \tau)^2 \int_{\xi \in \mathbb{Z}} \frac{w^2(\xi)}{w^2(0)} \frac{1}{h^2} K^2 \left( \frac{\xi - \xi_2}{h_2} \right) f_Z(\xi) f_Z(\xi_2) d\xi_1 d\xi_2
\]
by standard use of change of variables and Assumptions A.7 and A.9. The $U$-statistic representation in (30), together with the form of asymptotic variance $\tilde{\sigma}_{0r}^2$, implies that $Th^{d/2}_2 A_{1T} = Th^{d/2}_2 \overline{A}_{1T} + o_p(1) \overset{d}{\to} \mathcal{N}(0, \tilde{\sigma}_{0r}^2)$.

Observing that by using almost the same steps as in proving the asymptotic normality of $Th^{d/2}_2 A_{1T}$, we can prove that $Th^{d/2}_2 A_{2T}$ converges in distribution to a normal variable, and therefore $Th^{d/2}_1 A_{2T} = O_p(1)$. Thus, $Th^{d/2}_2 A_T = Th^{d/2}_2 A_{1T} + \left( h^{d/2}_2 / h^{d/2}_1 \right) \left( Th^{d/2}_1 A_{2T} \right) + o_p(1) \overset{d}{\to} \mathcal{N}(0, \tilde{\sigma}_{0r}^2)$ by the assumption $h^2_2 = o \left( h^2_1 \right)$ in A.9.

A consistent estimator of $\tilde{\sigma}_{0r}^2$ is given by
\[
\tilde{\sigma}_{0r}^2 = 2\tau^2 (1 - \tau)^2 \frac{1}{T(T-1)} \sum_{t=1}^{T} \sum_{s=1, s \neq t}^{T} \frac{w^2(Z_{t-1})}{w^2(0)} \frac{1}{h^2} K^2 \left( \frac{Z_{t-1} - Z_{s-1}}{h_2} \right).
\]
The term $\tilde{\sigma}_{0r}^2$ can also be written into a standard $U$-statistic form with a symmetrized kernel
\[
H_T(Z_{t-1}, Z_{s-1}) = 2\tau^2 (1 - \tau)^2 \left( \frac{w^2(Z_{t-1})}{w^2(0)} \frac{1}{h^2} K^2 \left( \frac{Z_{t-1} - Z_{s-1}}{h_2} \right) + \frac{w^2(Z_{s-1})}{w^2(0)} \frac{1}{h^2} K^2 \left( \frac{Z_{s-1} - Z_{t-1}}{h_2} \right) \right).
\]
Note that in contrast to (30), $\tilde{\sigma}_{0r}^2$ is a non-degenerate second order $U$-statistic and by the usual Hoeffding decomposition, one can show that $\tilde{\sigma}_{0r}^2 = \tilde{\sigma}_{0r}^2 + o_p(1)$.

Finally, observing that by Taylor expansion of $\ln y$ around 1 (i.e. $\ln y \approx y - 1$) and using the asymptotic equivalence of $\tilde{C}_r$ to $C_r = E[\rho_r(X_t - m_{1\tau}(Z_{t-1}))w(Z_{t-1})]$ stated in Lemma 4 of Appendix B, together with Slutsky’s theorem, we have
\[
Th^{d/2}_2 C_r(\overline{Y} \to X) = Th^{d/2}_2 \left( \frac{T^{-1} \sum_{t=1}^{T} \rho_r(X_t - \overline{m}_{1\tau}(X_{t-1}))w(Z_{t-1})}{T^{-1} \sum_{t=1}^{T} \rho_r(X_t - \overline{m}_{1\tau}(X_{t-1}))w(Z_{t-1}) - 1} \right) + o_p(1)
\]
\[
= C_r^{-1} Th^{d/2}_2 A_T + o_p(1)
\]
\[
\overset{d}{\to} \mathcal{N}(0, \sigma_{0r}^2),
\]
where $\sigma_{0r}^2 := \tilde{\sigma}_{0r}^2 / C_r^2$. It is straightforward to show that $\tilde{\sigma}_{0r}^2 / \tilde{C}_r^2$ is a consistent estimator for $\sigma_{0r}^2$.

Thus, our test statistic $\tilde{\gamma}_r = Th^{d/2}_2 C_r(\overline{Y} \to X) / \tilde{\sigma}_{0r} \overset{d}{\to} \mathcal{N}(0, 1)$. This ends the proof of Theorem 2. □

Proof of Proposition 3: This result can be shown by following the same steps as in the proof of Theorem
2. Noting that, under the fixed alternative hypothesis $H_1$ in (16), we have
\[
\frac{1}{T} \sum_{t=1}^{T} \rho_r(X_t - \bar{m}_{1r}(X_{t-1}))w(Z_{t-1}) - \frac{1}{T} \sum_{t=1}^{T} \rho_r(X_t - \bar{m}_{1r}(Z_{t-1}))w(Z_{t-1}) \\
= \left( \frac{1}{T} \sum_{t=1}^{T} \rho_r(X_t - \bar{m}_{1r}(X_{t-1}))w(Z_{t-1}) - \frac{1}{T} \sum_{t=1}^{T} \rho_r(X_t - m_{1r}(Z_{t-1}))w(Z_{t-1}) \right) \\
+ A_T + B_T + C_T \\
:= D_T + A_T + B_T + C_T,
\]
where the last three terms $A_T$, $B_T$, and $C_T$ are as defined before in the proof of Theorem 2. Following the same arguments as those in Theorem 2, $Th_2^{d/2} (A_T + B_T + C_T) = O_p(1)$. As a matter of fact, one can furthermore prove that all $A_T$, $B_T$ and $C_T$ are of order $o_p(T^{-1/2})$, see the proof of lemma 3 in Noh et al. (2013). On the other hand, under $H_1$ of causality, the weak law of large numbers yields immediately
\[
D_T = E \left[ \rho_r(X_t - \bar{m}_{1r}(X_{t-1}))w(Z_{t-1}) \right] - E \left[ \rho_r(X_t - m_{1r}(Z_{t-1}))w(Z_{t-1}) \right] + o_p(1) \\
= E \left[ \rho_r(X_t - m_{1r}(Z_{t-1}))w(Z_{t-1}) \right] \left( E \left[ \rho_r(X_t - \bar{m}_{1r}(X_{t-1}))w(Z_{t-1}) \right] - 1 \right) + o_p(1) \\
= E \left[ \rho_r(X_t - m_{1r}(Z_{t-1}))w(Z_{t-1}) \right] C_T(Y \rightarrow X) + o_p(1) \\
:= C_T \times C_T(Y \rightarrow X) + o_p(1),
\]
where the third step follows by a Taylor expansion of $\ln y$ around 1.

Therefore, since under $H_1$, $C_T(Y \rightarrow X) > 0$, or equivalently, $Pr \left[ m_{1r}(Z_{t-1}) = \bar{m}_{1r}(X_{t-1}) \right] < 1$, we have
\[
Th_2^{d/2} C_T(Y \rightarrow X) = Th_2^{d/2} T^{-1} \sum_{t=1}^{T} \rho_r(X_t - \bar{m}_{1r}(X_{t-1}))w(Z_{t-1}) - T^{-1} \sum_{t=1}^{T} \rho_r(X_t - \bar{m}_{1r}(Z_{t-1}))w(Z_{t-1}) \times [1 + o_p(1)] \\
= C_T^{-1} \left[ Th_2^{d/2} D_T + Th_2^{d/2} (A_T + B_T + C_T) \right] \times [1 + o_p(1)] \\
= Th_2^{d/2} C_T(Y \rightarrow X) \rightarrow \infty.
\]

Alternatively, under $H_1$ of causality, one can simply apply the consistency result in Proposition 2 to show that $C_T(Y \rightarrow X)$ converges in probability to $C_T(Y \rightarrow X) > 0$, and consequently $Th_2^{d/2} C_T(Y \rightarrow X)$ will diverge to infinity under our assumptions.

On the other hand, following arguments similar to those we have used in the proof of the consistency of estimator $\hat{\sigma}_{0r}^2$ to the asymptotic variance $\sigma_{0r}^2$ in Theorem 2 under the null hypothesis, we can show that $\hat{\sigma}_{0r}^2 := \frac{\hat{\sigma}_{0r}^2}{\hat{C}_r} = O_p(1)$ under the alternative hypothesis of no causality. Proposition 3 follows then from $Th_2^{d/2} C_T(Y \rightarrow X) \rightarrow \infty$ and $\hat{\sigma}_{0r} = O_p(1)$ as $T \rightarrow \infty$. Hence, the test $\hat{b}_r = Th_2^{d/2} C_T(Y \rightarrow X)/\hat{\sigma}_{0r}$ is diverging to infinity at the rate $Th_2^{d/2}$ and is consistent. $\Box$
Proof of Proposition 4: First, following similar arguments as in Theorem 2 and Proposition 3, with the only exception that the term $D_T$ defined in (31) now takes a different form. Specifically, we can show that under the local alternatives given in (19),

$$Th_2^{d/2} \left( \frac{1}{T} \sum_{t=1}^{T} \rho_T(X_t - \hat{m}_{1T}(X_{t-1}))w(Z_{t-1}) - \frac{1}{T} \sum_{t=1}^{T} \rho_T(X_t - \hat{m}_{1T}(Z_{t-1}))w(Z_{t-1}) - D_T \right)$$

$$:=Th_2^{d/2} (A_T + B_T + C_T) \overset{d}{\rightarrow} \mathcal{N}(0, \hat{\sigma}_{0T}^2),$$

with $A_T$, $B_T$, $C_T$, and $\hat{\sigma}_{0T}^2$ given in the proof of Theorem 2.

Second, under the local alternative hypotheses $H_1(\delta_T)$, using the second order Taylor expansion, one can calculate that

$$D_T = E \left[ \rho_T(X_t - \hat{m}_{1T}(X_{t-1}))w(Z_{t-1}) \right] - E \left[ \rho_T(X_t - \hat{m}_{1T}(Z_{t-1}))w(Z_{t-1}) \right] [1 + o_p(1)]$$

$$= E \left[ \rho_T(X_t - \hat{m}_{1T}(Z_{t-1}) + \delta_T \Delta_T(Z_{t-1})w(Z_{t-1}) \right] - E \left[ \rho_T(X_t - \hat{m}_{1T}(Z_{t-1}))w(Z_{t-1}) \right] [1 + o_p(1)]$$

$$= \delta_T E \left[ \Delta_T(Z_{t-1})w(Z_{t-1}) \right] \rho(\varepsilon_{1t}) - \frac{\delta_T^2}{2} E \left[ \Delta_T^2(Z_{t-1})w(Z_{t-1})g(Z_{t-1}) \right] [1 + o_p(1)]$$

$$= \delta_T^2 E \left[ \Delta_T^2(Z_{t-1})w(Z_{t-1})f_{\varepsilon_{1|\hat{Z}}} \right] [1 + o_p(1)],$$

where $g(\hat{z}) = \partial E[\rho(\varepsilon_{1t})|Z_{t-1}] = \frac{\hat{z}}{\partial \theta} = -f_{\varepsilon_{1|\hat{Z}}}(0|\hat{z})$, and the fourth step follows by law of iterated expectations and $E[\rho(\varepsilon_{1t})|Z_{t-1}] = 0$ in Assumption A.3. Consequently, with $\delta_T = \left(T h_2^{d/2}\right)^{-1/2}$, we have

$$Th_2^{d/2} C_T \overset{d}{\rightarrow} \mathcal{N}(\gamma, \sigma_{0T}^2)$$

under the local alternatives with

$$\gamma = C_T^{-1} \lim_{T \to \infty} \mathbb{E} \left[ \Delta_T^2(Z_{t-1})w(Z_{t-1})f_{\varepsilon_{1|\hat{Z}}} \right].$$

This concludes the proof of Proposition 4. □

Proof of Theorem 3: The asymptotic validity of our bootstrap procedure can be proved using similar arguments to those used in the proof of Theorem 2, with the term $A_{1T}$ replaced by its bootstrapped version $A_{1T}^*$ using the bootstrapped sample $\{(X_{t}^*, Y_{t}^*)\}_{t=1}^{T}$. Conditionally on $\{(X_t, Y_t)\}_{t=1}^{T}$ and using Theorem 1 of Hall (1984), we obtain the bootstrap validity result in Theorem 3. □

Proof of Theorem 4: The proof is similar to the proof of Theorem 1 and a sketched proof is provided.

Denote $\hat{d}_1(W_{t-1}) = (\hat{\beta}_r - \beta_r)W_{t-1}$ and $\hat{d}_2(X_{t-1}) = \hat{m}_{1T}(X_{t-1}) - \hat{m}_{1T}(X_{t-1})$. Note the following
Following the same arguments as in the proof of Theorem 2, it can be shown that the expansion holds,

\[
\frac{1}{T} \sum_{t=1}^{T} \rho_r \left( X_t - \tilde{\beta}_r W_{t-1} - \hat{m}_{1r}(X_{t-1}) \right) w(Z_{t-1})
\]

\[
= \frac{1}{T} \sum_{t=1}^{T} \rho_r \left( X_t - \tilde{\beta}_r W_{t-1} - \hat{m}_{1r}(X_{t-1}) \right) w(Z_{t-1})
\]

\[
- \frac{1}{T} \sum_{t=1}^{T} \left( \hat{m}_{1r}(X_{t-1}) - \hat{m}_{1r}(X_{t-1}) \right) w(Z_{t-1}) \varphi(\varepsilon_{1t}) - \frac{1}{T} \sum_{t=1}^{T} \left( \hat{\beta}_r - \hat{\beta}_r \right) W_{t-1} w(Z_{t-1}) \varphi(\varepsilon_{1t})
\]

\[
- \frac{2}{T} \sum_{t=1}^{T} \left( X_t - \tilde{\beta}_r W_{t-1} - \hat{m}_{1r}(X_{t-1}) \right) \left\{ \left( \hat{a}_1(W_{t-1}) + \hat{a}_2(X_{t-1}) > \varepsilon_{1t} > 0 \right) \left( \hat{a}_1(W_{t-1}) + \hat{a}_2(X_{t-1}) < \varepsilon_{1t} < 0 \right) \right\} w(Z_{t-1})
\]

\[
:= \frac{1}{T} \sum_{t=1}^{T} \rho_r \left( X_t - \tilde{\beta}_r W_{t-1} - \hat{m}_{1r}(X_{t-1}) \right) w(Z_{t-1}) + E_T + F_T + G_T
\]

\[
= \frac{1}{T} \sum_{t=1}^{T} \rho_r \left( X_t - \tilde{\beta}_r W_{t-1} - \hat{m}_{1r}(X_{t-1}) \right) w(Z_{t-1}) + o_p(T^{-1/2})
\]

where \( E_T = F_T = G_T = o_p(T^{-1/2}) \) can be proved using the steps in the proof of lemma 3 in Noh et al. (2013) and by noting that \( \max_{t \in I(w)} |\hat{a}_1(W_{t-1})| = O_p(T^{-1/2}) \) for bounded support. Moreover, the asymptotic representation for

\[
\frac{1}{T} \sum_{t=1}^{T} \rho_r \left( X_t - \tilde{\beta}_r W_{t-1} - \hat{m}_{1r}(Z_{t-1}) \right) w(Z_{t-1}) = \frac{1}{T} \sum_{t=1}^{T} \rho_r \left( X_t - \beta_r W_{t-1} - m_{1r}(Z_{t-1}) \right) w(Z_{t-1}) + o_p(T^{-1/2})
\]

can be obtained using the same arguments as Lemmas 3 and 4. The proof then follows by using the equality that \( \hat{a} b^{-1} = ab^{-1} + b^{-1} \left( (\hat{a} - a) - (b - b) ab^{-1} \right) \). □

**Proof of Theorem 5:** Consider the following decomposition of \( \rho_r(\cdot) \):

\[
\frac{1}{T} \sum_{t=1}^{T} \rho_r \left( X_t - \tilde{\beta}_r W_{t-1} - \hat{m}_{1r}(X_{t-1}) \right) w(Z_{t-1}) - \frac{1}{T} \sum_{t=1}^{T} \rho_r \left( X_t - \tilde{\beta}_r W_{t-1} - \hat{m}_{1r}(Z_{t-1}) \right) w(Z_{t-1})
\]

\[
= \frac{1}{T} \sum_{t=1}^{T} \left[ \left( \hat{m}_{1r}(Z_{t-1}) - m_{1r}(Z_{t-1}) \right) - \left( \hat{m}_{1r}(X_{t-1}) - m_{1r}(X_{t-1}) \right) \right] w(Z_{t-1}) \varphi(\varepsilon_{1t})
\]

\[
+ \frac{1}{T} \sum_{t=1}^{T} \left( \hat{\beta}_r - \beta_r \right) \left( \hat{\beta}_r - \beta_r \right) W_{t-1} w(Z_{t-1}) \varphi(\varepsilon_{1t}) + \text{higher order terms}
\]

\[
:= H_T + I_T + \text{higher order terms}
\]

Following the same arguments as in the proof of Theorem 2, it can be shown that \( Th^{1/2} H_T \overset{d}{\to} N(0, \hat{\sigma}_r^2) \) and \( Th^{1/2} I_T = \left[ \sqrt{T} \left( \hat{\beta}_r - \beta_r \right) - \sqrt{T} \left( \hat{\beta}_r - \beta_r \right) \right] h^{1/2} O_p(1) = o_p(1) \) by root-\( T \) consistency properties of linear
coefficients estimators $\hat{\beta}_r$ and $\hat{\beta}_r$. Therefore,

$$Th_2^{d/2} C_{\tau}^{PL} (Y \rightarrow X | W)$$

$$= (C_{\tau}^{PL})^{-1} Th_2^{d/2} H_T \times [1 + o_p(1)]$$

$$\xrightarrow{d} N(0, \sigma_{0\tau}^{PL}),$$

which proves that $Th_2^{d/2} C_{\tau}^{PL} (Y \rightarrow X | W)$ converges to a normal distribution under the null of no causality in the presence of control variables $W$. □

**Appendix B**

In this appendix, we provide four auxiliary lemmas which are useful to prove our main results in Appendix A.2. In the first lemma, the uniform Bahadur representation for the estimator of the restricted conditional quantile function $\hat{m}_{1\tau}(\bar{x})$ based on a $p$-th order local polynomial approximation using bandwidth $h_1$ is derived. Please notice that the proofs of the following Lemmas 1-4 can be obtained using similar arguments as in lemmas 2 and 3 in Noh et al. (2013) [or using results in Kong et al. (2010), see their corollary 1, lemmas 8 and 10, respectively], and they are therefore omitted.

**Lemma 1:** Let $\bar{\epsilon}_1$ be an $N \times 1$ vector with its first element given by 1 and all others 0. Suppose Assumptions A.1-A.9 in Appendix A.1 hold and $h_1 = O(T^{-\kappa_1})$ with $\kappa_1 > 1/(2p + 2 + d_1)$. Then, with probability one, we have

$$\hat{m}_{1\tau}(\bar{x}) - \hat{m}_{1\tau}(\bar{x}) = -\epsilon'_1 \frac{H_1^{-1}}{Th_1^{d_1}} S_{T,p}(\bar{x}) \sum_{t=1}^T K_{h_1}(X_{t-1} - \bar{x}) \phi(\epsilon_{1t}) \mu(X_{t-1} - \bar{x}) + R_T,$$

where $\epsilon_{1t} = X_t - \hat{m}_{1\tau}(\bar{X}_{t-1})$ is the restricted error and $R_T = o_p \left( (Th_1^{d_1})^{-1/2} \right) \text{ uniformly in } \bar{x} \in D_X$ and $D_X$ is the compact support of the weighting function $w(\cdot)$ with respect to the part of $X$.

Analogously, the $q$-th order local polynomial estimator of the unrestricted conditional quantile function $m_{1\tau}(\bar{z})$ using bandwidth $h_2$, say $\hat{m}_{1\tau}(\bar{z})$, can be defined accordingly as in Section 5 and its uniform Bahadur representation can be obtained similarly and is stated in the next lemma. Note that Lemma 1 is only a special case of Lemma 2.

**Lemma 2:** Denote $d = d_1 + d_2$. Let $\bar{\epsilon}_1$ be an $N \times 1$ vector with its first element given by 1 and all others 0. Suppose Assumptions A.1-A.9 in Appendix A.1 hold and $h_2 = O(T^{-\kappa_2})$ with $\kappa_2 > 1/(2q + 2 + d)$. Then, with probability one, we have

$$\hat{m}_{1\tau}(\bar{z}) - m_{1\tau}(\bar{z}) = -\epsilon'_1 \frac{H_2^{-1}}{Th_2^{d_2}} S_{T,q}(\bar{z}) \sum_{t=1}^T K_{h_2}(Z_{t-1} - \bar{z}) \phi(\epsilon_{1t}) \mu(Z_{t-1} - \bar{z}) + R_T,$$

where $\epsilon_{1t} = X_t - m_{1\tau}(Z_{t-1})$ is the unrestricted error and $R_T = o_p \left( (Th_2^{d_2})^{-1/2} \right) \text{ uniformly in } \bar{z} \in D$ and $D$ is the compact support of the weighting function $w(\cdot)$. 

39
On the other hand, to derive the Bahadur representation of \(C_r(\widehat{Y} \to X)\), we need to investigate the asymptotic behaviour of \(T^{-1} \sum_{t=1}^{T} \rho_r(X_t - \widehat{m}_1(X_{t-1}))w(Z_{t-1})\) [resp. \(T^{-1} \sum_{t=1}^{T} \rho_r(X_t - \widehat{m}_1(Z_{t-1}))w(Z_{t-1})\)], which is stated in the next two lemmas. Again, the proof of Lemma 3 is similar to the one of Lemma 4.

**Lemma 3:** Suppose Assumptions A.1-A.9 in Appendix A.1 hold, \(p > d_1/2 - 1\) and \(h_1 = O(T^{-\kappa_1})\) with \(1/(2p + 2 + d_1) < \kappa_1 < 1/(2d_1)\). Then,

\[
\frac{1}{T} \sum_{t=1}^{T} \rho_r(X_t - \widehat{m}_1(X_{t-1}))w(Z_{t-1}) - E[\rho_r(X_t - \widehat{m}_1(X_{t-1}))w(Z_{t-1})]
\]

\[
= \frac{1}{T} \sum_{t=1}^{T} \rho_r(X_t - \widehat{m}_1(X_{t-1}))w(Z_{t-1}) - E[\rho_r(X_t - \widehat{m}_1(X_{t-1}))w(Z_{t-1})] + o_p(T^{-1/2}).
\]

**Lemma 4:** Let \(d = d_1 + d_2\). Suppose Assumptions A.1-A.9 in Appendix A.1 hold, \(q > d/2 - 1\) and \(h_2 = O(T^{-\kappa_2})\) with \(1/(2q + 2 + d) < \kappa_2 < 1/(2d)\). Then, we have

\[
\frac{1}{T} \sum_{t=1}^{T} \rho_r(X_t - \widehat{m}_1(Z_{t-1}))w(Z_{t-1}) - E[\rho_r(X_t - \widehat{m}_1(Z_{t-1}))w(Z_{t-1})]
\]

\[
= \frac{1}{T} \sum_{t=1}^{T} \rho_r(X_t - \widehat{m}_1(Z_{t-1}))w(Z_{t-1}) - E[\rho_r(X_t - \widehat{m}_1(Z_{t-1}))w(Z_{t-1})] + o_p(T^{-1/2}).
\]
